(Received 16 April 2001; revised 4 December 2001; accepted 14 January 2002)

To establish the validity of the boundary-element method (BEM) for modeling scattering by swimbladder-bearing fish, the BEM is exercised in several ways. In a computation of backscattering by a 50-mm-diam spherical void in sea water at the four frequencies 38.1, 49.6, 68.4, and 120.4 kHz, agreement with the analytical solution is excellent. In computations of target strength as a function of tilt angle for each of 15 surface-adapted gadoids for which the swimbladders were earlier mapped, BEM results are in close agreement with Kirchhoff-approximation-model results at each of the same four frequencies. When averaged with respect to various tilt angle distributions and combined by regression analysis, the two models yield similar results. Comparisons with corresponding values derived from measured target strength functions of the same 15 gadoid specimens are fair, especially for the tilt angle distribution with the greatest standard deviation, namely 16°.

The present aim is to describe the two basic models that have been applied to fish. These have been based principally on simple shapes such as the sphere at low frequencies and prolate ellipsoid, or the actual shape, called “mapping” method by McClatchie et al. Only the first two models have exact solutions in general, thus the matter of approximation must be addressed, at least for realistic shapes at relatively high frequencies, where the wavelength is not very long compared to the size of significant scattering organs.

The deformed fluid-cylinder model has been very popular and has been the object of a major study. Essentially, it reduces an observed shape to a series of axisymmetric cylinders. The method has been realized by Clay and Horne for Atlantic cod, McClatchie and Ye for orange roughy, McClatchie et al. for barracouta (Thysites attun), red cod (Pseudophycis bachus), and southern blue whiting (Micromesistius australis), and Sawada et al. for walleye pollock (Theragra chalcogramma). Excluding the cited case of Atlantic cod, each model has been based entirely on the swimbladder as a deformed cylinder. The swimbladder is important in the Atlantic cod model, but this includes other parts of the fish too, again represented as finite cylinders.

The exact shape of the swimbladder has also been considered more directly in the Kirchhoff-approximation model for pollack and saithe (Pollachius virens), walleye pollock, and southern blue whiting.

All of the high-frequency models cited so far are similar in their neglect of diffraction. To remedy this, the boundary-element method (BEM) has begun to be applied in modeling scattering by swimbladder-bearing fish.

In addition to treating diffraction, the BEM allows use of general conditions on the swimbladder boundary surface, with explicit representation of the internal fluid. Thus the BEM can also be used to study pressure-dependent effects, which are otherwise precluded by the standard Kirchhoff-approximation model. Establishing the validity of the BEM for a pressure-release surface is important for the larger program being introduced.

The present aim is to describe the two basic models that...
represent the swimbladder by its actual shape, namely the Kirchhoff-approximation model and the BEM, but both assuming a pressure-release boundary condition. Application of these to historical swimbladder morphometric data is described. Independent validation of the two methods is addressed, and computations with the two models are compared.

II. KIRCHHOFF-APPROXIMATION MODEL

In the Kirchhoff approximation, the field on the scattering surface is assumed to be known a priori. For a swimbladder-bearing fish at rather high frequencies, or wavelengths which are rather small compared to the maximum length of the swimbladder, the fish is represented by a pressure-release surface conforming to the inner wall of the swimbladder.23,24 The normal component of particle velocity on the scattering surface is assumed to be equal to that of the incident field on the directly insonified part of the surface, and zero on the geometrically shadowed part of the surface.

Mathematically, the farfield backscattering amplitude in this approximation is

\[ f = \lambda^{-1} \int_S \exp(2i\mathbf{k} \cdot \mathbf{r}) \mathcal{H}(\mathbf{k} \cdot \hat{n}) \mathbf{k} \cdot \hat{n} dS, \]  

where \( \lambda \) is the acoustic wavelength, \( \mathbf{k} \) is the wave vector in the source or backscattering direction \( \mathbf{k} = \mathbf{k}/k \), \( \mathbf{r} \) is the position vector of the surface element with infinitesimal area \( dS \), \( \hat{n} \) is the unit normal to \( dS \) at \( \mathbf{r} \), and \( \mathcal{H}(x) \) is the Heaviside step function with values 1 for \( x > 0 \), \( \frac{1}{2} \) for \( x = 0 \), and 0 for \( x < 0 \).

The integration in Eq. (1) is performed numerically using Gauss quadrature over curvilinear surface elements on which the position vector \( \mathbf{r} \) is interpolated quadratically from nodal values. The integrand is evaluated at each integration, or Gauss, point using the interpolated value of \( \mathbf{r} \). A good representation of the phase, as given by the factor \( \exp(2i\mathbf{k} \cdot \mathbf{r}) \), depends on the separation of these points. If the integration were to be performed by primitive Riemann summation, then the points should be closer than about \( \lambda/16 \). However, the point-separation condition is undoubtedly relaxed by the use of Gauss quadrature. If the polynomial fit assumed by Gauss quadrature is of order 2 or higher, a good representation of the wave form should be obtained for a point separation up to \( \lambda/6 \). For seven-point quadrature on six-node triangular elements, with nodes at the corners and midsides of the elements, the Gauss point separation is at most 0.8 times the nodal separation. A similar relationship exists for eight-node quadrilateral elements using \( 3 \times 3 \) or more Gauss points. A condition for validity of the numerical integration, that the nodal separation should be less than \( \lambda/5 \), is therefore tentatively suggested. This translates to a condition that the element side-to-wavelength ratio should be less than 2/5. In order to give commonality with the corresponding condition in the case of the boundary-element method, to be discussed in Sec. III, the slightly stricter ratio of 1/3 is adopted in this paper for assessing the frequency range of validity of a given mesh. The element meshes are described in Sec. IV.

The backscattering cross section is

\[ \sigma = 4\pi |f|^2. \]  

The target strength is the logarithmic expression of \( \sigma \),

\[ TS = 10 \log \left( \frac{\sigma}{4\pi r_0^2} \right), \]  

where \( r_0 \) is a reference distance, assumed here to be 1 m.

III. BOUNDARY-ELEMENT METHOD

To develop the acoustic boundary-element method (BEM), the wave equation for the pressure \( p \) is reduced to the Helmholtz form by assuming the harmonic time dependence \( \exp(i\omega t) \), where \( \omega \) is the angular frequency in radians per second, hence \( \nabla^2 p + k^2 p = 0 \), where \( k = \omega/c \) is the wave number. This is rewritten in integral form, in which the pressure at any point is expressed in terms of the acoustic pressure and normal displacement \( u \) on the scattering surface \( S \). This surface is subdivided into elements, and the pressure and displacement distributions on \( S \) are represented by discrete values, \( p_i \) and \( u_i \), respectively, at each node \( i \) associated with these elements. The standard Helmholtz integral equation suffers from singularities at certain critical frequencies, which are dense at high frequencies. To overcome this problem, the integral is combined with a second integral developed from the first by differentiating with respect to the normal direction at the surface.31 In principle, the two equations are combined by adding the standard form evaluated at each node of each element to a multiple \( \alpha \) of the normal-derivative form evaluated at the centroid of that element in the local coordinate system.11 The resulting equation can be written thus:

\[ \mathbf{Ap} = \mathbf{Bu} - \mathbf{p}_{\text{inc}} - \alpha \frac{\partial \mathbf{p}_{\text{inc}}}{\partial n}. \]  

If the swimbladder is assumed to be ideally pressure-releasing, \( p_i = 0 \) for all \( i \), and Eq. (4) can be solved directly for the nodal normal displacements:

\[ \mathbf{u} = \mathbf{B}^{-1} \left( \mathbf{p}_{\text{inc}} + \alpha \frac{\partial \mathbf{p}_{\text{inc}}}{\partial n} \right). \]  

The coefficients of the matrix \( \mathbf{B} \) are assembled from local matrices pertaining to each element of the mesh. With the calculation point of the Helmholtz integral taken at node \( i \), with position \( \mathbf{r}_i \), integration over element \( m \) provides the following coefficients in the standard formulation:

\[ b_{mn}^{(1)}(\mathbf{r}_i) = \rho \omega^2 \int_{S_m} N_m(q) \cos \theta_{mn} G(\mathbf{r}_i, q) dS_q, \]  

where \( \rho \) is the fluid density, \( \mathbf{q} \) is the position vector of the integration point on the element surface \( S_m \), \( G \) is the Green’s function, given by \( G(\mathbf{r}_i, q) = e^{-ik|\mathbf{r}_i - q|}/4\pi |\mathbf{r}_i - q| \), \( n \) is the local nodal label, and \( N_m(q) \) \((n = 1,2,...,6) \) for triangular elements, \( n = 1,2,...,8 \) for quadrilateral elements) are the shape functions, which are of the standard second-order (quadratic) form.52 The factor \( \cos \theta_{mn} \) is included to allow for the deviation \( \theta_{mn} \) of the normal to the element \( m \) at local node \( n \) from the mean normal at that node. The mean normal at a node is

TABLE I. Properties of the 15 specimens whose swimbladder surfaces have been remapped, based on the original mapping (Ref. 23) with \( n_{\text{tri}} \), small triangular facets, by \( n_{\text{elem}} \), curvilinear elements with \( n_{\text{nods}} \) nodes. The nodal separation distance such that 99% of neighboring separations are smaller and the maximum nodal separation are both specified.

</table>

defined as the average of the normals at the node on all contiguous elements weighted by the respective differential surface area.

The normal-derivative form of the Helmholtz integral equation, calculated at the centroids \( \mathbf{r}_i \) of the elements, similarly provides coefficients as follows:

\[
b_m^{(2)}(\mathbf{r}_i) = \rho \omega^2 \int_{S_m} N_m(\mathbf{q}) \cos \theta_{mn} \frac{\partial G(\mathbf{r}_i, \mathbf{q})}{\partial \mathbf{r}_j} dS_q,
\]

where the normal derivative is evaluated at the centroid. These are combined with the previous coefficients by adding a multiple of \( b_m^{(2)}(\mathbf{r}_i) \) for all elements \( n \) on which global node \( i \) lies, i.e.,

\[
b_m(\mathbf{r}_i) = b_m^{(1)}(\mathbf{r}_i) + \alpha_i \sum_{l: i \in \mathbf{S}_j} b_m^{(2)}(\mathbf{r}_i),
\]

where the combination factor \( \alpha_i \) is taken to be \(-i/kM_i\), where \( M_i \) is the number of elements meeting at node \( i \).\textsuperscript{11,33,34}

The use of the centroids, rather than the nodes, as the calculation points for the normal-derivative form is found to be sufficient to overcome the problem of the critical frequencies while not increasing the computational effort unduly.\textsuperscript{11}

The integrals are evaluated numerically using Gauss quadrature.

The coefficients \( b_m(\mathbf{r}_i) \) are assembled into the global matrix \( \mathbf{B} \) by summing the coefficients that correspond to the same global node, thus

\[
B_{ij} = \sum_{m,n:C(m,n) = j} b_m(\mathbf{r}_i),
\]

where \( C(m,n) \) is the global node label of local node \( n \) on element \( m \). The source terms in Eq. (4) are evaluated thus:

\[
\mathbf{p}_{\text{inc}}(\mathbf{r}_i) + \alpha_i \sum_{l: i \in \mathbf{S}} \frac{\partial \mathbf{p}_m(\mathbf{r}_i)}{\partial \mathbf{r}_j}.
\]

Given the solution for \( u \) from Eq. (5), the scattered pressure at any exterior point \( \mathbf{r} \) is obtained from the standard integral equation by calculating coefficients similar to \( b_m^{(1)}(\mathbf{r}_i) \) but with \( \mathbf{r}_i \) replaced by the position vector \( \mathbf{r} \):

\[
b_m^{(3)}(\mathbf{r}) = \rho \omega^2 \sum_{j} \int_{S_m} N_m(\mathbf{q}) \cos \theta_{mn} G(\mathbf{r}, \mathbf{q}) dS_q,
\]

and then

\[
p(\mathbf{r}) = -b^{(3)}(\mathbf{r}) \cdot \mathbf{u}.
\]

The far-field backscattering amplitude at finite range \( r \) is

\[
f(r) = \frac{|r p(\mathbf{r})|}{|P_{\text{inc}}|}.
\]

The far-field backscattering amplitude \( f \) is the limit of \( f(r) \) as \( r \) approaches infinity. Expressions for the backscattering cross section and target strength are derived by substituting \( f(r) \), or \( f \), in Eqs. (2) and (3), respectively.

The elements used here are quadrilaterals and triangles of the quadratic isoparametric type, in which both the geometric and acoustic quantities are interpolated from the nodal values using quadratic shape functions, the nodes being situated at the vertices and mid-sides.\textsuperscript{32} As a general guide, good representation of the acoustic variables is obtained if the lengths of the sides of the elements are less than one-third of a wavelength. The accuracy of geometrical representation depends on the degree of undulation of the surface, but it should be noted that the quadratic interpolation allows the elements to be curved. Further details of the formulation and equations can be found in Ref. 11.

IV. SWIMBLADDER MORMOPOMETRY

The origin of the morphometric data is a study performed in 1980\textsuperscript{15} on surface-adapted specimens of pollack and saithe, described briefly in Table I. Each specimen was anesthetized, tethered, and acoustically measured at each of four frequencies, nominally 38, 50, 70, and 120 kHz, prior to shock-freezing and microtoming in the sagittal plane, hence
parallel to the main axis, according to the method of Ona. The thickness of successive photographed sections was 100 μm. Each swimbladder section was digitized as a set of coordinates describing the outline of the swimbladder, and the surface of each swimbladder was represented by a mesh consisting of flat triangular facets.

Because of the use of curvilinear quadrilaterals and triangles in the BEM, new meshes have been produced for each of the specimens using a semiautomatic process. First, the contours of the swimbladder in planes perpendicular to the major axis of the fish, and hence perpendicular to the microtomed sections, are determined at intervals along the major axis, by finding the points of intersection of each plane with the original digitized sections. Quadrilateral and triangular elements are then fitted between neighboring contours. Where required, nodes are interpolated using cubic splines. This method allows the fineness of the mesh to be controlled by the choice of the separation between the contours and the nodal separation on each contour. Some manual fitting of elements is required where the swimbladder branches into separate lobes.

A further reason for the remapping exercise was to reduce the number of nodes in order to facilitate matrix operations inherent to the BEM. The resulting meshes have fewer elements than the original triangular meshes, but this is offset by the allowance for curvature of the surface. An example of one of the meshes is visualized in Fig. 1. The new meshes have been used in computations with the Kirchhoff-approximation model in parallel with the BEM.

Details of the meshes are listed in Table I. For each mesh, the maximum distance between neighboring nodes is shown in the final column, column 11; however, a better indication of the degree of fineness of each mesh is given in column 10, namely the limit of nodal spacing which is satisfied by 99% of the distances between pairs of neighboring nodes. At 120.4 kHz the nodal spacing, to satisfy the \( \lambda/6 \) condition for accuracy of the BEM and Kirchhoff-approximation model, should be less than 2.03 mm. All of the meshes except that for specimen 201 are well within this limit even on the basis of the maximum nodal spacing found in the mesh. Detailed analysis of the mesh for specimen 201 reveals that the \( \lambda/6 \) condition is satisfied for all but two pairs of neighboring nodes out of 4530 such pairs.

V. INDEPENDENT VALIDATION OF MODELS

A cogent form of validation of the Kirchhoff-approximation model is the direct comparison of model computations and measurement results for the same fish specimens used in the morphometry. This work is documented in detail in Ref. 23 but in which the integration in Eq. (1) is performed by the primitive Riemann summation, with evaluation of the integrand at the centroid of each triangular facet.

Validation of the BEM has already been documented for a series of cases in which analytical solutions are available. Three of those described in Ref. 11 are cited. (1) The forward scattered pressure for a plane wave incident on a rigid sphere has been computed. The agreement over the \( ka \) range from 0 to 10 is excellent, without discrepancies at the critical frequencies that arise in the standard formulation, which lacks the normal component included in Eq. (4). (2) The backscattered pressure from a rigid sphere has been computed under similar conditions, again with excellent agreement, while avoiding discrepancies at the critical frequencies. (3) As an illustration, the radiation impedance of a uniformly vibrating circular piston of radius \( a \) in the end face of a cylinder of radius 2\( a \) and height 4\( a \) over the \( ka \) range from 0 to 5 has been computed and compared with the analytical solution for a piston in an infinite baffle. With allowance for the difference between the two problems, the agreement is quite good.

An additional trial of the BEM has been designed specifically for the present study. A spherical void of radius 25 mm is assumed to be immersed in sea water of sound speed 1470 m/s and density 1025 kg/m\(^3\). The size has been chosen for having an area of 7854 mm\(^2\), which is roughly 20% greater than the area of the mesh spanning the surface of the largest swimbladder, No. 207, as represented by 1487 elements (4363 nodes), with an area of 6524 mm\(^2\). Meshes have been generated by subdividing each spherical triangle of a geodesic icosahedron into four subtriangles, subdivided again to get a mesh of 320 elements (642 nodes) and subdivided once more to get a mesh of 1280 elements (2562 nodes). The latter mesh has a maximum nodal separation of 2.06 mm, which is just outside the limit of 2.03 mm required by the \( \lambda/6 \) condition at 120.4 kHz.

The same example provides a trial for the Kirchhoff approximation, since the integration in Eq. (1) can be performed analytically for the spherical shape:

![Image](https://example.com/image1.png)

FIG. 1. Boundary-element mesh of the swimbladder to specimen No. 205 of Ref. 23, shown in both oblique and dorsal views. The model has 1107 elements and 3181 nodes. The meshed swimbladder length is 141 mm.
\[ f = (4k)^{-1}\{-1 + \cos(2ka) + 2ka \sin(2ka) \}
+ i[\sin(2ka) - 2ka \cos(2ka)] \}, \]

where \( a \) is the sphere radius. Comparison of the numerical and closed-form analytic solutions at the frequencies 38.1, 49.6, 68.4, and 120.4 kHz demonstrates agreement to within 0.01 dB for the 2562-node sphere. Further exercise of the Kirchhoff model reveals significant divergence of the numerical solution from the exact solution at about 180 kHz for the 2562-node sphere and at about 90 kHz for the 642-node sphere. The truth of this last statement is evident in the target strengths and forward-scattering strengths are presented in Table III. Corresponding target strengths and forward-scattering strengths are presented in Table IV.

It is noted that, for certain frequencies and mesh sizes, the condition for the nodal spacing discussed in Secs. II and III, namely that this should be less than \( \lambda/6 \), is violated. The results for these cases are included in Tables II–IV but are shown in italics. The limit is only just exceeded by the finer mesh at 120.4 kHz.

VI. COMPARISON OF MODEL COMPUTATIONS

The target strength for an immersed void with the shape of the swimbladder shown in Fig. 1 has been computed as a function of tilt angle for both the dorsal and ventral aspects at each of four frequencies. Both the Kirchhoff-approximation model and BEM have been examined. The computational results are shown with the measured functions in Fig. 3.

The same computations have been repeated for the mapped swimbladder shapes of all 15 gadoid specimens listed in Table I. In order to reduce these to manageable proportions, the several functions have been averaged with respect to normal distributions \( g(\theta) \) of tilt angle \( \theta \), with mean \( \bar{\theta} \) and standard deviation \( s_\theta \):

\[ \bar{\sigma} = \int g(\theta)\sigma(\theta)d\theta / \int g(\theta)d\theta', \]

where the integration has been performed over the range \( [\bar{\theta} - 3s_\theta, \bar{\theta} + 3s_\theta] \). For the measured target strength functions, values at tilt angles outside the range \([-45^\circ, 45^\circ]\) were not available, and for such angles the value of \( \sigma \) at the nearest angle limit has been used.

Computations have been performed for each of four normal distributions of tilt angle. The paired values \( (\bar{\theta}, s_\theta) \) are \((0^\circ, 0^\circ)\), \((0^\circ, 5^\circ)\), \((0^\circ, 10^\circ)\), and \((-4.4^\circ, 16^\circ)\). Because of the effect of perspective, by which the apparent tilt angle of a fish changes as it is observed at different positions in the plane transverse to the acoustic axis, the effective values of \( s_\theta \) are larger than the nominal ones. The values shown above have been adjusted for the perspectival effect for a circular beam of 5\(^\circ\) beamwidth measured between the half-power points. The effective standard deviations for the four cases are 2.5\(^\circ\), 5.5\(^\circ\), 10.2\(^\circ\), and 16\(^\circ\).23

The target strength corresponding to each averaged backscattering cross section, denoted \( \overline{TS} \), has been computed by substituting the value of \( \bar{\sigma} \) from Eq. (14) in Eq. (3). The values of \( \overline{TS} \) have been regressed on fish length \( l \) in centimeters according to the regression equation,

\[ \overline{TS} = 20 \log l + b, \]

where the regression coefficient \( b \) is expressed in decibels. The standard error of the regression has been computed for each derived regression equation. The results are shown in Tables V and VI.

VII. DISCUSSION

A. Model validation computations

To validate the BEM for application to the gadoid swimbladder, a 25-mm-radius spherical void in sea water has been chosen as a test case in order to have a shape for which a rather simple analytical solution exists and whose surface area is greater than that of the largest swimbladder in the data set. Finite-element representation of the sphere by a subdivided icosahedron has allowed both the BEM and Kirchhoff approximation to be computed according to Eqs. (12) and (1), respectively.

Because of the finiteness of the facets, there is an effect due to axial orientation, which is indicated in Table II. The BEM is seen to be quite accurate for the two meshes that were chosen. Sensitivity to axial orientation is negligible as long as the maximal nodal separation does not exceed \( \lambda/6 \). The Kirchhoff-approximation model is exercised with the identical meshes but performs less well than the BEM; it is inherently different, as is proved by the difference in respective exact and analytical solutions for the two models for this special shape. The variability with orientation is notable for the coarser mesh.
mersed in water of density 1025 kg/m³ and sound speed 1470 m/s, as given
by the series solution. Kirchhoff integral through the closed-form expression
in Eq. (13), numerical Kirchhoff approximation using a surface mesh with
642 nodes, and boundary-element method using the same 642-node surface mesh.

Both backscattering and forward-scattered pressure amplitudes for the same boundary-element meshes are shown in
Table III for the BEM, with close agreement with the analytical result except for the coarser mesh at the highest frequency of 120.4 kHz, where the nodal spacing greatly exceeds λ/6. Again, the Kirchhoff approximation performs less well. Differences in the two models are also evident in the logarithmic measures presented in Table IV.

The apparent improvement in performance of the Kirchhoff approximation at the highest frequency of 120.4 kHz is illusory, since, as noted previously, the closed-form analytic solution for the Kirchhoff-approximation model for the spherical void differs from the exact series solution. In fact, the approximation solution given by Eq. (13) oscillates about a cycle frequency of about 30 kHz, corresponding to the condition 2Δka = π, where Δk describes the change in wave number that satisfies the equality, as shown in Fig. 2. The corresponding Kirchhoff-approximation model results for the two meshes agree well with each other except at the highest frequency, where the separation in neighboring Gauss points for the coarser mesh, using seven-point integration, is about λ/4, thus exceeding λ/6. The nodal spacing for the same mesh is about λ/3, also exceeding both the λ/5 and λ/6 conditions mentioned in Secs. II and III, respectively.

The Kirchhoff approximation, since it requires only a direct integration, is computationally much faster than the BEM, which requires the inversion of a complex matrix of size equal to the square of the number of nodes. Above about 4000 nodes, the BEM becomes cumbersome, at least on current desk-type workstation-level computers. In contrast, the Kirchhoff approximation could be exercised with far more elements than used here and thus, in principle, could be more amenable to computation at higher frequencies. However, the approximation has inherent limitations, such as the neglect of diffraction over the surface of the scattering shape or body, if most serious at relatively low frequencies.

To summarize, the BEM results agree well with the analytical results for the cases of 2562 and 642 nodes, deviating significantly only for nodal separations exceeding λ/6. The Kirchhoff approximation fares relatively poorly in comparison; nonetheless, it agrees to within about 1.2 dB at 38.1 kHz and within about 0.6 dB at the three highest frequencies.

### B. Swimbladder-shape-based computations

The detailed computations of target strength as a function of tilt angle are shown for a single specimen, No. 205, in Fig. 3. Both the Kirchhoff-approximation model and BEM results are shown for the swimbladder as represented in Fig. 1. The respective measured target strength functions are also shown.

Both similarities and deviations are observed. Significantly for this work, the Kirchhoff-approximation and BEM results are quite similar. Comparisons against the measured function reveal similarities in overall structure, but with sizable discrepancies over certain angular regions, both in amplitude and degree of structure. Nonetheless, in the displayed case of specimen No. 205, it can be imagined that some average backscattering cross sections will be similar in magnitude.

Statistical combination of the individual averages in the regression analysis described by Eq. (15) reveals strong similarities, especially for the tilt angle distribution with largest

0.4 dB, with average difference about 0.2 dB. At 120.4 kHz, the respective numbers are 0.8 and 0.5 dB.

A survey of the overall results in Tables V and VI may suggest some systematic differences with the regression coefficient \( b \) and standard error. Caution is advised in the interpretation of apparent systematic differences, however, because the computational results are not all independent. While 16 sets of computations are presented for each aspect, they apply to a total of only four frequencies, which is closer to the number of degrees of freedom for the respective aspect. Were data available at other frequencies, the possible presence of systematic differences among measurements and models might reveal the influence of other parts of the fish in modifying backscattering by the swimbladder alone.

A further internal comparison is possible for the Kirchhoff approximation. The mapping of the swimbladder is derived from the original mapping by flat triangular facets. The new mapping, for consistency with the BEM, contains fewer but curvilinear elements spanning the swimbladder surface. A detailed comparison of corresponding values for the regression coefficient \( b \) in Eq. (15) reveals a greatest discrepancy of 0.2 dB, with median discrepancy of 0.1 dB, for the dorsal aspect. In ventral aspect the greatest discrepancy is 0.1 dB, with median discrepancy less than 0.05 dB.

### C. Summary of comparisons

Earlier validation exercises with the BEM have been supplemented by a new example, that of a spherical void for

which a simple analytical solution is known. Results with the Kirchhoff approximation are poorer. Nonetheless, in the case of the swimbladder-shape-based computations, the Kirchhoff approximation, when exercised with the curvilinear elements used in the BEM, yields results that agree well with earlier computations carried out using meshes with larger numbers.
of flat elements.

While use of the BEM does not improve the earlier agreement of Kirchhoff-approximation computations with the measured target strength functions, the two models do show a basic agreement. Differences in predictions, as expressed through the regression coefficient in Eq. (15), are less than 1 dB in all cases except at 38.1 kHz where the greatest difference is 1.3 dB. There is some expectation that the discrepancy might be largest at the lowest frequency, for the Kirchhoff approximation assumes high frequencies. An offsetting factor, however, is the effective element side-to-wavelength ratio, which increases with frequency, decreasing the applicability, hence accuracy, of the approximation.

D. Future work

The BEM performs similarly to the Kirchhoff approximation for the frequencies and swimbladder sizes considered here. This is reassuring, since both models have the great

advantage over other models in being able to treat a complicated shape without compromise, in principle, based on a finite-element representation of the surface.

The BEM can, however, do much more than the Kirchhoff-approximation model. (1) It can, for example, treat lower frequencies, for diffraction is addressed in a fundamental manner through the integral-equation solution of the wave equation described in Sec. III. (2) The BEM can also treat the case of a gas-filled swimbladder under the influence of hydrostatic pressure without having to make assumptions about the applicable boundary conditions. (3) A third advantage of the model is its capacity to treat heterogeneous structures, as long as the heterogeneities can be demarked by surfaces within which the acoustic properties are uniform. Thus, the BEM can predict scattering by a swimbladder-bearing fish in which the swimbladder and other structures, e.g., liver, reproductive products, and fish tissue surrounding the swimbladder, are explicitly represented. (4) It is noted that the BEM can address finite-scattering-range effects, without having to assume an infinite range, as is done in typical farfield-only models.

The applicability of the BEM to organisms other than swimbladder-bearing fish is evident. Thus the BEM can address scattering by the organisms conveniently classified by Stanton as deformed fluid cylinders, deformed elastic-shelled spheres, and bubble plus tissue, as represented, for example, by euphausiids, gastropods, and siphonophores, respectively.40 Significantly, there is no need to approximate shape or boundary conditions, for the model is numerical.

Some of the effects mentioned here may be addressed in a future work. These may also include bistatic scattering, which is allowed by both the BEM and Kirchhoff-approximation model, as well as other models, such as the deformed-cylinder model.10
