Abstract: This paper treats $L_1$ adaptive hovering control of an unmanned surface vehicle in a station-keeping mode where a region of zero control authority and under-actuation are main challenges. Low-speed and reversing dynamics are identified from full scale sea trials, and parameter uncertainty is estimated. With significant parameter variation, an $L_1$ adaptive controller is employed for heading control. The $L_1$ family of controllers allows for several topologies and an architecture is suggested that suits heading control of a vessel, the requirements of which differ from that of previous $L_1$ literature. The control design is tackled directly in discrete time to allow a fast embedded implementation in the vehicle. Analysis of robustness, tracking performance and wave disturbance response are detailed in the paper.

Keywords: $L_1$ adaptive control, unmanned vehicle, system identification, discrete time control

1. INTRODUCTION

Personal water crafts (PWC) are capable of fast and agile manoeuvring and provide endurance over long distances making them suitable for complex autonomous missions. Certain missions may require station keeping as one of the use-modes, which is achieved through heading and speed control at low speed forward and aft.

The realization of station keeping for the PWC is certainly a challenge since the system is underactuated. The vehicle has an azimuth impeller equipped with an elevator, which can be used to change the vertical direction of the impeller jet. This actuation is perfect at high forward speed to execute fast manoeuvres; however at low speed the controllability of the system reduces.

Control of underactuated vehicles has received a great attention (see e.g. Pettersen and Fossen (2000); Fossen and Strand (2001); Blanke (2005); Pereira et al. (2008)), but it still is an open and interesting control problem. Fossen and Strand (2001) proposed the weather optimal heading control, where the marine craft is steered to be on a virtual circle headed towards the center. A set of model parameters were at hand for the considered vessel and a PD regulator was designed using the backstepping design methodology with the inclusion of integral action.

For the PWC there is no model readily available, and the identification of the system dynamics solely relies on full scale motion data always affected by induced oscillations in the wave frequency range. This results in significant parameter variation, which calls in for robust and adaptive control strategies.

The development of the $L_1$ adaptive control theory (Ho-vakimyan and Cao, 2010) has allowed for design of controllers ensuring uniform closed loop transient response over a wide range of parametric uncertainties, while guaranteeing robustness and stability. Svendsen et al. (2012) took the first steps towards a fully autonomous PWC by designing and implementing two independent $L_1$ adaptive controllers for cruise and steering control at medium to high speed.

This paper proposes a low speed adaptive heading controller suitable for station keeping. The architecture of the $L_1$ adaptive controller is modified in order to best fit the heading control problem, and the controller is completely and directly designed in discrete time to enable fast embedded implementation in the vehicle. Robustness and performance of the proposed heading controller is analyzed w.r.t. model uncertainties and disturbances.

2. SYSTEM CONFIGURATION

The water jet vehicle is a modified Sea-Doo GTX 215 personal water craft (see Fig. 1), whose physical specifications are listed in table A.1. A radio link between the vehicle and a ground station allows remote command of three servos, which control the throttle, the azimuthal angle of the water jet, and the elevator angle of a blade constraining the angle of attack of the pressurized water stream w.r.t. the horizontal.

The elevator angle or deflection $\beta$ of the blade w.r.t. the horizontal is in the interval $\beta \in [0^\circ; 55^\circ]$ and a deflection $\beta$ corresponds to a deflection of the water jet of $2\beta$, as illustrated in Fig. 1. Similarly the azimuth $\delta$ controls the horizontal direction of the water jet, giving a moment
around the $z$-axis. The maximum angular deflection is $\delta_{\text{max}} = 15^\circ$ to each side with a rate limit of $\dot{\delta} \leq 30^\circ/s$.

3. PWC REVERSING DYNAMICS

For low speed operations such as station keeping where the speed is below $3\,\text{m/s}$ the personal water craft behaves as a fully displaced vessel; hence the influence of the vertical dynamics into the manoeuvring characteristic is negligible. For larger ships it is assumed that the heave, roll and pitch dynamics into the manoeuvring characteristic is negligible.

The 3 DOF surge-sway-yaw linear manoeuvring model is formulated according to (Clarke and Horn, 1997; Fossen, 2001). Let $\eta \triangleq [N, E, \psi]^T$ be the generalized position vector w.r.t. an Earth-fixed frame, and $\nu \triangleq [u, v, r]^T$ the generalized velocity vectors w.r.t. a body-fixed frame. The PWC dynamics in the horizontal plane is then given by

$$\dot{\eta} = R(\psi) \nu$$

where $M$ is the mass-inertia matrix including rigid-body and added mass; $N(u_0)$ contains the linear contribution from the frictional and Coriolis-centripetal forces and moments evaluated at the forward speed $u_0$; $\tau_s$ and $\tau_c$ are the vectors of generalized control and environmental forces; $R(\psi)$ is the rotation matrix that maps velocities from body- to the Earth-fixed frame.

Assuming that the water craft has $xz$-plane symmetry and that the mass distribution is even, surge can be decoupled from steering. Therefore $M$ and $N$ in (2) read

$$M = \begin{bmatrix} m - X_u & 0 & 0 \\ 0 & m - Y_v & mx_y - Y_s \\ 0 & mx_y - N_r & I_z - N_r \end{bmatrix}$$

$$N(u_0) = \begin{bmatrix} -X_u & 0 & 0 \\ 0 & -Y_v & mu_0 - Y_c \\ 0 & -N_u & mx_yu_0 - N_r \end{bmatrix}$$

where $m$ is the mass of the vehicle, $I_z$ is the rigid body inertia around the $z$-axis, $x_y$ is the horizontal coordinate of the centre of gravity w.r.t. the origin of the body-fixed manoeuvring frame ($z$-down), and $X(\cdot), Y(\cdot), N(\cdot)$ are the hydrodynamic derivatives.

Said $T$ the thrust force, the control input vector $\tau_c = [\tau_x^c, \tau_y^c, \tau_z^c]^T$ is given by

$$\tau_c \triangleq b(\delta, \beta)T = \begin{bmatrix} \cos \delta \cos(2\beta) \\ -\sin \delta \cos(2\beta) \\ L_{\delta} \sin \delta \cos(2\beta) \end{bmatrix} T$$

$$\approx \begin{bmatrix} \cos(2\beta) \\ -\delta \cos(2\beta) \\ L_{\delta} \delta \cos(2\beta) \end{bmatrix} T$$

as the azimuthal angle $|\beta| \leq 15^\circ$; hence $\sin \delta$ and $\cos \delta$ are replaced by their first order approximation. In (3) $L_{\delta}$ is the $x$-distance from the center of buoyancy to the nozzle head.

Equation (3) shows the effect of the elevator deflection on the manoeuvring of the PWC:

- $0 < \beta < \pi/4$ causes a forward thrust force from the impeller
- for $\pi/4 < \beta < \beta_{\text{max}}$ the thrust changes sign and causes a reversing thrust
- $\beta = \pi/4$ is a singular configuration in the controllability space since the input vector $b(\delta, \beta)$ is zero

The availability of only the motion data gathered during full scale sea trials obviously precludes the possibility of identifying the coefficients of the matrices $M$ and $N(u_0)$. Therefore the identification of the low-speed reversing dynamics relies on linear output models parametrized in terms of time constants and gains. Hence the action of environmental forces/moments $\tau_c$ is modelled as output disturbances.

3.1 Low-Speed Surge Dynamics Identification

The decoupled surge dynamics reads

$$\dot{u}(t) = -\frac{X_u}{m - X_u} u(t) + f(h, t) \cos(2\beta(t)),$$

where $f(h, t)$ is the body $x$ component of the thrust. The throttle handle $h$ has been constrained to the constant value $h = 1$, it is therefore assumed $f(h, t) = f$ is constant. Equation (4) can be rewritten in transfer function form as

$$u(s) = \frac{K_u}{T_u s + 1 + g_\delta(s)},$$

where $g_\delta(s)$ is the Laplace transform of $\cos(2\beta(t))$; $K_u \triangleq f$ is the steady state surge gain for a constant $\beta$; $T_u \triangleq (X_u/(m - X_u))^{-1}$ is the time constant.

The parameters $K_u$ and $T_u$ are estimated from full scale data collected in response to elevator steps. The identified model is

$$M_{u,g} : u(s) = \frac{2.46}{5.58s + 1} g_\delta(s)$$

whose fit to the data set in identification is 92.3%, and in validation is 85.4%. Figure 2 shows the comparison between the full scale data and the surge model $M_{u,g}$ for the identification and validation data sets.

3.2 Low-Speed Steering Dynamics Identification

The linear output yaw model associated to (2) is

$$r(s) = H_{\text{nom}}(s) \delta(s) + r_w(s), \quad H_{\text{nom}} = \frac{K_r}{T_r s + 1}$$

which is the first order Nomoto model (Nomoto et al., 1957) affected by external disturbances, where $K_r = -N_l D_n$, $T_r = (I_z - N_r) D_n$. 

Fig. 1. PWC with deflected elevator: a deflection $\beta$ causes the water jet to be deflected by an angle equal to $2\beta$,
However, since low complexity models are sought, and respect to the dynamics present on the full scale data. under-parametrization of the chosen model structure with analysis of these two indicators clearly addressed the such as parameter’s sign test and residual whiteness. The assessment of the identified Nomoto models, Standard methods of system identification have been used shown in Sec. 4.1.

4. TOWARDS STATION KEEPING

In the design towards a station keeping system, a heading controller is an important aspect. This section presents a step towards station keeping in projecting a discrete time $L_1$ adaptive heading controller for the PWC. Surge control can be performed using e.g. (Fossen and Strand, 2001; Pettersen and Fossen, 2000), and it is not be considered further in this paper.

4.1 Forced Yaw Acceleration

A new control input is defined as the forced yaw acceleration

$$\bar{\alpha}_S^\circ(\beta, \delta) \triangleq -\frac{N_S(\beta)}{I_z - N_s} \delta,$$

where $N_S(\beta) = T L_n \cos(2\beta)$ is a function of the elevator angle. By including $N_s$ in the new control input the sign of the input gain is preserved. This guarantees that the input gain does not switch sign during system’s operation, which is needed in order to design the adaptive controller.

Figure 4 shows the dependency of the physical torque gain $N_S$ on the elevator deflection. $N_s$ has been estimated by

$$D_n = \frac{T_n}{I_z - N_s} \Rightarrow N_S = \frac{K_n}{D_n} \tag{10}$$

where $I_z$ has been computed considering the PWC as a rigid rod with most of the mass placed at the center, and the added inertia $N_s < 0$ has been assumed constant and equal to 80% of $I_z$ ($I_z - N_s \approx 460$ kg m$^2$).

The indirect estimate of $N_S$ is strongly affected by the inconsistency in the estimate of $T_n$ for values of $\beta$ close to zero. Hence the values of $N_S$ are scattered, determining an uncertainty in the magnitude of $\bar{\alpha}_S^\circ$. This uncertainty is modelled as

$$\bar{\alpha}_S^\circ(\beta, \delta) = \omega \bar{\alpha}_S^\circ(\beta, \delta), \ \omega \in [\omega_{\text{min}}, \omega_{\text{max}}] \tag{11}$$

where $\omega$ is an uncertain input gain and $\omega_{\text{max}} > \omega_{\text{min}} > 0$.  

Fig. 2. Identification and validation of the surge dynamics from elevator steps: (top) model $M_1$ identified for $\psi \approx 260^\circ$; (bottom) model $M_1$ validated for $\psi \approx 0^\circ$.

with $D_n = \left( (m x_a - Y_r)u_0 - N_r \right)^{-1}$. The wave disturbance $r_w(s)$ is modelled as the output of a second order filter driven by white noise $\varepsilon_w(t)$

$$r_w(s) = \frac{\kappa_w s^8}{s^2 + 2\lambda_w \omega_w s + \omega_w^2} \varepsilon_w(s). \tag{8}$$

The model (7) is used for identifying the low-speed manoeuvring dynamics of the PWC. The wave model (8) is introduced to take into account the presence of wave motion in the experimental data sets. The identification of the yaw dynamics is performed by using full scale motion data collected during 19 circular tests at different elevator angles $\beta$. The Box-Jenkins model structure (Box and Jenkins, 1970) is used to represent the dynamics (7), and the model’s parameters are estimated using the prediction error method (Ljung, 1999).

Figure 3 shows the estimated Nomoto model parameters with $\pm 1\sigma$ uncertainty. The estimates have generally a very low uncertainty, except for the two sea trials performed at $\beta \approx \pi/4$ when the vehicle is close to the controllability singularity. The estimate of the pole $1/T_n$ is not very consistent, i.e. experiments repeated at the same elevator angle do not provide similar values, especially for $\beta \approx 0$. This may address the influence of the low frequency component of the wave motion on the estimation of the PWC dynamics. Instead the estimate of the gain $\kappa_w / T_n$ is more robust, with the presence of only two outliers for $\beta = 0$. Figure 3 also shows the sign dependency of the input gain on the deflection of the elevator. This poses an important issue for the design of adaptive controllers, which requires the definition of a new control input, as shown in Sec. 4.1.

Standard methods of system identification have been used to assess the validity of the identified Nomoto models, such as parameter’s sign test and residual whiteness. The analysis of these two indicators clearly addressed the under-parametrization of the chosen model structure with respect to the dynamics present on the full scale data. However, since low complexity models are sought, and
This is fulfilled through a two step design: first a baseline frequencies range to reduce wear and tear of the actuator. The heading controller is designed for operation at the performance in presence of changes in system parameters.

The proposed architecture for the adaptive controller, which guarantees scalable transient filtering of the adaptive estimate, which ensures tracking of the command of the adaptive controller. The adaptive controller is undertaken in discrete time. The proposed architecture results directly in discrete time. The proposed architecture springs from the design in Xargay et al. (2010) and uses the piecewise constant adaptive laws proposed in Cao and Hovakimyan (2009). However, to the authors’ knowledge this is the first attempt to tackle the design of the $L_1$ adaptive controller directly in discrete time. The proposed architecture results in

\[ u_{pd}(k) = - \sum_{i=0}^{k} h_f(k-i) (k_p \psi_c(i) + k_d r(i)) \]  

where $k_p$ and $k_d$ are the proportional and derivative gains, and $h_f(k)$ is the unit pulse response of the wavefilter

\[ H_f(z) = \frac{k_H (z^2 + 2 \xi_f \omega f z + \omega f^2)}{(z - e^{-\alpha \omega f T_s})(z - e^{-\beta \omega f T_s})} \]  

which limits the control actuation in response to high frequency wave induced motion.

$L_1$ Adaptive PD Augmentation Due to the physical correlation between heading angle and turning rate, the architecture of the $L_1$ adaptive controller is based only on the turning rate dynamics. Actually it is only the turning rate dynamics that can be uncertain, and that is directly affected by environmental disturbances, as shown in (1)-(2). Hence the yaw dynamics (12)-(13) is reduced to

\[ r(k) = f_{22} r(k) + g_2 (\omega_0 u_{pd}(k) + u_{ad}(k)) \]  

\[ y_{\zeta_1}(k) = r(k) \]  

where $a_0^V(k)$ is the yaw rate induced acceleration due to wind and waves.

The proposed $L_1$ architecture springs from the design proposed in Xargay et al. (2010) and uses the piecewise constant adaptive laws proposed in Cao and Hovakimyan (2009). However, to the authors’ knowledge this is the first attempt to tackle the design of the $L_1$ adaptive controller directly in discrete time. The proposed architecture results in

State predictor The state predictor is based on the reference model (16) and represents the desired closed loop dynamics

\[ \hat{r}(k+1) = f_{22} \hat{r}(k) + g_2 (\omega_0 u_{pd}(k) + u_{ad}(k) + \hat{\sigma}(k)) \]  

where $\hat{\sigma}$ is the estimate of the model uncertainty, and $\omega_0$ is the nominal value of the uncertain gain $\omega$.

Adaptation law The estimate of the unmodelled dynamics relies on the prediction error $\tilde{r}(k) = r(k) - \hat{r}(k)$ as

\[ \hat{\sigma}(k) = -g_2^{-1} f_{22} \tilde{r}(k) = -K_\sigma \tilde{r}(k) \]  

where $K_\sigma$ is the adaptation gain, which is clearly a function of the sampling time $T_s$ and the system parameters.

Control law The adaptive control signal $u_{ad}$ is a lowpass filtering of the adaptive estimate, which ensures tracking up to a chosen bandwidth

\[ u_{ad}(z) = -k D(z) \hat{\sigma}(z) \]  

where $k$ is the feedback gain, $D(z)$ is a lowpass filter containing a pure integrator, and $\hat{\sigma}(z)$ is the $Z$-transform of

\[ \hat{\sigma}(k) = (\omega_0 u(k) + \hat{\sigma}(k)) \]  

By choosing the lowpass filter as

\[ D(z) = \frac{k_1 (z + z_1)}{(z - 1)(z - p_1)} \]  

and assuming $\omega_0 = 1$ the control law then reduces to

\[ u(z) = -C(z) \hat{\sigma}(z) \]  

\[ C(z) = \frac{k k_1 (z + z_1)}{z^2 + (k k_1 - p_1 - 1) z + p_1 + k k_1 z_1} \]
The bandwidth of the filter $C(z)$ sets a clear trade-off between the adaptation to unmodelled dynamics and the sensitivity of the control signal to wave disturbances. The robustness properties of the adaptive controller are investigated by a frequency analysis showing the system performance in response to changes in the nominal plant.

For the calculations the plant is given a multiplicative uncertainty $\omega$, and it is converted to discrete time along with the state predictor

$$H_{pl}(z) = Z \{\omega/(T_n s + 1)\}$$

$$H_{sp}(z) = Z \{1/(T_n s + 1)\}$$

The discrete time $L_1$ adaptive controller is shown in Fig. 5. The relevant transfer functions, namely from reference to heading and from disturbance to forced yaw acceleration, are calculated to be

$$H_{\psi_{ref}}(z) = \frac{H_{pl}T_s k_p H_f (1 + H_{sp}K_a)}{d(z)}$$

$$H_{\alpha_{\psi_{ref}}} = \frac{1}{d(z)}(-C K_\alpha z - C K_\alpha + H_f k_D z - H_f k_D$$

$$+ H_f k_D H_{sp}K_a z - H_f k_D H_{sp}K_a$$

$$+ T_s H_f k_D + T_s H_f k_D H_{sp}K_a)$$

where

$$d(z) = (z - 1 + H_{sp}K_a z - C H_{sp}K_a z + C H_{sp}K_a$$

$$- H_{sp}K_a + H_{pl}T_s k_p H_f + H_{pl}k_D H_f z - H_{pl}k_D H_f$$

$$+ H_{pl}K_a C - H_{pl}K_a C + H_{sp}K_a H_{pl}T_s k_p H_f$$

$$+ H_{sp}K_a H_{pl}k_D H_f z - H_{sp}K_a H_{pl}k_D H_f)$$

The bandwidth of $C(z)$ gives a trade-off between adaptation to system’s changes and undesired actuation in response to wave motion.

4.3 Robustness Analysis of $L_1$ Adaptive Controller

The desired closed loop step response should have an overshoot less than 5%, and a rise time of approximately 4.2 seconds. Suitable parameters for the baseline controller achieving these requirements are listed in table B.1.

The performance of heading controller is first assessed by step changes. Figure 7 shows the scalability of the transient response of the $L_1$ adaptive heading controller. Figure 8 shows the performance of the PWC during an elevator step simulation. The elevator steps and causes the surge to change sign and thereby the input gain.

5. PERFORMANCE ASSESSMENT

Last the $L_1$ adaptive heading controller is tested against wave disturbances, as shown in Fig. 9. As expected the controller limits the use of control authority to counteract the wave motion, while regulating the heading around the desired value.
