Stability Boundaries for Offshore Wind Park Distributed Voltage Control

Mikkel P.S. Gryning, SM, IEEE, Qiuwei Wu, Member, IEEE, Łukasz Kocewiak, Member, IEEE, Hans Henrik Niemann, Karsten P.H. Andersen and Mogens Blanke, Senior Member, IEEE

Abstract—In order to identify mechanisms causing slow reactive power oscillations observed in an existing offshore wind power plant, and be able to avoid similar events in the future, voltage control is studied in this paper for a plant with a static synchronous compensator, type-4 wind turbines and a park pilot control. Using data from the actual wind power plant, all stabilizing subsystem voltage proportional-integral controller parameters are first characterized based on their Hurwitz signature. Inner loop current control is then designed using Internal Mode Control principles, and guidelines for feed forward filter design are given to obtain required disturbance rejection properties. The paper contributes by providing analytical relations between power plant control, droop, sampling time, electrical parameters and voltage control characteristics, and by assessing frequencies and damping of reactive power modes over a realistic envelope of electrical impedances and control parameters.

Index Terms—Reactive power control, voltage control, wind power plants, wind energy integration.

I. INTRODUCTION

FULL-SCALE back-to-back converters are used in large wind-turbines (WTs) to control active and reactive power [1]. Power electronic devices enable fast and independent control at the cost of increased complexity of wind power plants (WPPs) and the associated control systems [2]. Offshore turbines are connected to the transmission system through a medium-voltage (MV) sub sea cable network and a high voltage (HV) network from the point of common coupling (PCC). The WT control system design is intricate due to limited knowledge of the transmission system characteristics and, depending on the system topology, uncertain interconnection dynamics between distributed voltage controllers can pose a threat to overall system stability. This research was motivated by a stability issue that was encountered when a large WPP was commissioned.

Figure 1 shows the voltage control topology for the WPP studied here. The PCC voltage control system consists of voltage control at the WT low-voltage (LV) terminals and at the static synchronous compensator (STATCOM). The power plant control (PPC) provides a voltage reference to the WTs, which change reactive power, while the STATCOM operates autonomously. In this case, two systems seek to control the PCC voltage by injecting reactive power at electrically distant points. This could lead to unwanted interactions if the system parameters are not aligned [3].

The design of a voltage control strategy is limited by partial unknown network parameters and system dynamics [4]. If the estimation of the system parameters is poor, local voltage profile regulation can lead to reactive power oscillations [5]. Furthermore, local voltage control may influence voltage flicker, caused by unwanted interaction between individual control loops [6], [7]. An assessment of the static voltage stability of a power system considering all power controls was presented in [8], using singular values, but dynamics of interacting converter systems in a network affect the parameter range of stabilizing controls and instability could occur [9]. An analysis of local regulation of voltage profiles in distributed systems, considering WT capability curves, was treated in [4], who also addressed stability. Static provision of reactive power by a decentralized generation system was studied in [10], and as reactive power capability is a function of active power output [11], combined power optimization and reactive power control was studied in [12].

As local voltage is controlled by regulating the balance of reactive power, WPP dynamic voltage stability requires fast distributed reactive sources [13]. Back-to-back or matrix converters are the prevalent technologies used for this control [14], where the output waveform of the converter is a function of grid voltage, and feed forward is used to improve disturbance rejection [15]. The feed forward is low pass
filtered in a tradeoff between noise, over current protection and stability [16]. Hence, literature has mainly studied single control loops but has not addressed the entire topology of a WPP system.

Addressing the entire hierarchy of controls that establish the voltage control of a WPP, this paper investigates possible causes of reactive power oscillations based on a case where poorly-damped responses were observed. Different mechanisms are identified and stability boundaries are calculated in order to find root causes for the observed behaviors. The probable causes are discussed and a procedure is suggested to obtain robust design of WPP distributed voltage control. It is shown how the complex Hurwitz test, which was used for analysis of a current controlled generator in [17], can be extended to find the stabilizing parameter space for a complex WPP control with several interacting control loops.

The contributions of the paper are: (A) to describe a systematic approach to finding root causes to an observed phenomena; (B) to propose a methodology to identify the main contributing factors to the phenomena; (C) identify the stability boundaries of WT voltage source inverter (VSI) and STATCOM control; (D) to suggest a systematic approach to control design that assures sufficient robustness such that reactive power oscillations are avoided in new WPPs.

The paper first introduces the gathered data and proposes two possible causes. The methodology used to investigate the propositions is presented in Section III. Section IV focuses on tuning of the WT VSI control. The results from Section IV is applied in Section V to the STATCOM control. Section VI describes the effect of parameter variation on reactive power oscillations. Finally, Section VII discuss the contributory causes of the observed oscillation followed by conclusions.

II. Problem Formulation

An incident of unacceptable reactive power oscillations in a WPP was observed. The phenomenon appeared as underdamped oscillations at the PCC shown in Fig. 2. Iterative adjustment of converter controller gains and disconnecting WTs from the PCC attenuated the oscillation amplitude and partly remedied the problem, however, the root cause of the problem was never clarified. The attenuation indicates a problem with the initial tuning of voltage controllers, or an unwanted coupling between the WTs and the STATCOM. This paper seeks to clarify the possible causes of the marginal phenomena and cause hereof is thus obtainable by modeling the implicated systems, and identifying the range of controller parameters for which the system remains stable. As the electrical network and other control loops affect the range of stabilizing controller parameters, an analytical solution is required to establish bounds. From the Hurwitz signature of the closed-loop system, an analytical expression for stability exists based on the number of distinct non-negative roots of the associated polynomial [18]. The number of distinct non-negative roots as a function of system parameters is guaranteed by an analytical solution of the Sturm sequence components.

The solution is verified numerically by root-locus analysis or time domain simulation in the identified range of controller parameters.

III. Methodology

This is achieved through a study of the WPP voltage control structure shown in Fig. 1.

A. Parameter Bounds

Given a rational polynomial with real coefficients $Q(j\omega) = N(j\omega)/D(j\omega)$ with $N(j\omega)$ having no zeroes on the $j\omega$ axis, the polynomial can be rewritten as,

$$Q(j\omega) = Q_r(\omega) + jQ_i(\omega) = Q_e(-\omega^2) + \omega Q_o(-\omega^2). \quad (1)$$

The total phase change, i.e. the Hurwitz signature, of $Q(j\omega)$ is [19],

$$\sigma(Q) = \left( \sum_{j=1}^{1} (-1)^{j-1-j} \text{sgn}[Q_r(\omega_j)] \right) \text{sgn}[Q_i(\infty^-)]. \quad (2)$$
where \( l - 1 \) is the number of real non-negative zeroes of \( Q_f(\omega) \). Let \( \text{deg}(D(s)) = n, \text{deg}(N(s)) = m \leq n \) and \( K(s) = k_p + k_i/s \), closed loop stability of the feedback interconnection \( Q(s) \), \( K(s) \) is equivalent to having \( n+1 \) zeroes of the characteristic polynomial \( \delta(s) \) in the open left half plane (LHP). It follows,

\[
\sigma(\delta(s)) \geq n + 1. \tag{3}
\]

The polynomial \( \nu(s) = \delta(s)N(-s) \) exhibits the parameter separation property such that [19],

\[
\nu(s) = \nu_c(s^2, k_i) + s\nu_o(s^2, k_p). \tag{4}
\]

Stability of \( \delta(s) \) follows from,

\[
\sigma(\nu(s)) = \sigma(\delta(s)) + \sigma(N(-s)) = (n - m) + 1 + 2z^+, \tag{5}
\]

where \( z^+ \) denotes the number of right half plane (RHP) zeroes of \( Q(s) \). The Hurwitz signature is expanded as,

\[
\sigma(\nu) = j(i_0 - 2i_1 + \cdots + (-1)^{l}2i_l + (-1)^{l+1}i_{l+1}), \quad j = \text{sign}(\nu(s)(0^+, k_p^*)), \tag{6}
\]

and let \( \Gamma \) define the distinct strings of integers \( \{i_0, i_1, \ldots, i_{l+1}\} \) satisfying (5). The stabilizing set of integral gains \( k_i \), given a \( k_p \) such that \( \nu(s) \) has \( l \) distinct non-negative zeroes, is given by the linear inequalities [19],

\[
\nu_c(-\omega^2, k_i)i_t > 0, \quad l \geq (n - m + 1)/2 - 1. \tag{9}
\]

The full stabilizing set \( \Omega(k_p, k_i) \) can thus be found by guaranteeing \( l \) distinct non-negative roots of \( \nu(s) \) and solve the set of linear inequalities. It is proposed in this paper to extend the stabilizing sets theory by guaranteeing the required number of distinct non-negative real roots by manipulation of the Sturm sequence. The number of distinct non-negative real roots in a univariate polynomial in the interval \([0, \infty)\) can be determined by the number of sign changes in the Sturm sequence evaluated at the end points of the interval [20]. Let \( p_1 \) be the number of sign changes at \( \omega_0 \equiv 0 \) and \( p_2 \) at \( \omega_{l+1} \equiv \infty \), the number of distinct non-negative real roots are \( l = p_1 - p_2 \) [20].

IV. PROPOSITION I: WIND TURBINE VOLTAGE CONTROL

A model of the WT voltage control and the effect of parameter variation on system modes is investigated in this section. Bounds on the current control parameters are established for proper performance and disturbance rejection, and subsequently used in the voltage control analysis.

A. System Model

A VSI with an inductor-capacitor-inductor (LCL) and trap filters is shown in Fig. 3. The LCL-filter is approximated by an inductor filter for low frequencies [21]. The filters and the transformer represent the plant \( G_1(s) \), and the grid is the disturbance dynamics \( G_d(s) \). The current loop dynamics are given by,

\[
L_f \frac{d\hat{i}^{dq}}{dt} + R_{f_f}^{dq} = u_i^{dq} - E^{dq} + DL_f \omega_p i^{dq}, \tag{10}
\]

where,

\[
\omega_g = \begin{bmatrix}
0 & \omega_0 \\
-\omega_0 & 0
\end{bmatrix}, \quad D = \begin{bmatrix}
0 & 1 \\
1 & 0
\end{bmatrix}. \tag{11}
\]

The rotating reference frame (RFF) axis coupling and grid voltage disturbance \( E^{dq} \) is canceled by introducing feedback of the output current \( i_f^{dq} \) and feed forward of the measured grid disturbance \( E_m^{dq} \) as,

\[
u_c^{dq} = u_i^{dq} - C(s)E_m^{dq} + DL_f \omega_p i_f^{dq}. \tag{13}
\]

B. Current Control Design

The current control structure consists of a PI controller for zero steady state error and a notch filter, \( B \), as shown in Fig. 4. Let \( e_i = i_f - i_f \), and \( \bar{K}_2(s) = k_{pc} + k_{ic}z \) the reference voltage is,

\[
u_i^c = \bar{K}_2(s)e_i + C(s)E \pm j\omega L_{fi} f. \tag{17}
\]

The closed loop transfer functions from reference \( i_f^c(s) \) to output \( i_f(s) \) and from disturbance \( E(s) \) to \( i_f(s) \) are given by,

\[
i_f(s) = \frac{(k_{pc} + k_{ic})i_f^c(s)}{D(s)}, \quad i_f(s) = \frac{(s\tau_2 + 1)E(s)}{(s + \alpha_f)D(s)}, \quad D(s) = L_f \tau_2 s^3 + (R_f + L_f) s^2 + (Bk_{pc} + R_f) s + Bk_{ic}. \tag{18}
\]

The system for control synthesis is represented as a first-order plus time delay model, \( G_1(s) \),

\[
G_1(s) = \frac{1}{R_f (L_f / \tau_2 + \tau_2 / 2)s + 1} e^{-\tau_2 / 2s}. \tag{19}
\]
By process inversion design, the controller parameters are given as [23].

\[ k_{pc} = \frac{(L_f + R_f(\tau_c/2))/\tau_c + \tau_s/2}{(\tau_c + \tau_s/2)/\tau_c} \]  
(20)

\[ k_{ic} = k_{pc}/(\min(L_f/R_f + \tau_s/2, 4(\tau_c + \tau_s/2)) \]  
(21)

where \( \tau_c \) is a tuning parameter for trade-off between output performance and robustness.

1) Parameter Bounds: The system bandwidth is constrained by the switching frequency \( f_s \), attenuation of harmonics, maximum gain \( K_{max} \), and system resonances [24]. Assuming small \( k_{ic} \) (20) and the closed-loop bandwidth trade-off,

\[ f_s = 0.2f_s \]

bound \( \tau_c \) for performance [25],

\[ \tau_c \geq \left\{ \begin{array}{ll} 
-50(\kappa_2 + L_f)R_f - \kappa_1 + 5\kappa_2\kappa_3 + 10L_f\kappa_3, & f_s/5 \\
\kappa_1 + 50R_f^2 + 2\kappa_1 \\
50R_f^2 + 2\kappa_1 \\
(\tau_s/2)(R_f - K_{max}) + L_f, \quad k_{pc} \leq K_{max}, 
\end{array} \right. \]  
(22)

where \( \kappa_1 \) through \( \kappa_9 \) are parameters given in [26]. Selecting \( \tau_c \) from bandwidth limitation of \( k_{pc} \) gives an upper bound on \( k_{ic} \),

\[ k_i \leq \frac{(25R_f^2 + \kappa_1^2)}{50(\kappa_3 - 5R_f)^2(\kappa_2 + 2L_f)}. \]  
(23)

2) Disturbance Rejection: The choice of low-pass filter coefficient \( \alpha_f \) determines the bandwidth. Converter over current protection requires small \( |v_f|^{max} \) for network disturbances [27]. This is achieved with large \( \alpha_f \) Parameters \( \alpha_f \) and \( k_p \) are respectively lower and upper bounded by bandwidth limitations. For sufficiently small \( \tau_s < 1ms \), the roots of \( D(s) \), \( z_p \), are governed by,

\[ z_p \in \mathbb{R}, \quad k_{ic} < (R_f^2 + k_{pc}^2 + 2R_fk_{pc})(4L_f)^{-1}, \]  
(24)

Bounding \( k_{ic} \) by (24) guarantees a damping of unity on all modes. The system response to a grid voltage step disturbance as a function of PI parameters and \( \alpha_f \) is,

\[ i(t) = \left( \frac{(\kappa_9 - \kappa_8)e^{2\kappa_1t} + \kappa_9 + \kappa_8}{\kappa_2 - \kappa_3} \right) - \left( \kappa_1 + \kappa_2 - \alpha_f \right) \kappa_9. \]  
(25)

The response has a global maximum at,

\[ t_{max} = \ln\left( \frac{2\kappa_5}{\kappa_3} \right)/\left( \alpha_f - \kappa_4 - \kappa_7 \right). \]  
(26)

If restrictions on \( t_{max} \) or \( |i|^{max} \) exist, \( \alpha_f \) should be selected from (26) or a contour plot of (25).

C. Voltage Control Analysis

The structure of \( K_1(s) = k_{pv} + k_{iv}/s \) is a PI-controller. The reference signal is,

\[ v_f(s) = K_1(s)(u_f^r(s) - u_f(s)). \]  
(27)

The closed loop system defined by (16) and (18) with input (27) has \( n = 5 \) and \( m = 2 \) which satisfies (9) for \( l \geq 1 \). The Sturm sequence \( \Psi(\omega) \) of \( \nu_0(\omega_0, k_{pv}) \) consist of four subsequent equal constants \( \alpha_0 \) with alternating signs,

\[ \alpha_0 = k_{pv} + 1/R_v, \]  
(28)

such that for \( k_{pv} \) in \( \mathbb{R} \) \{1\} \( R_v \}, p_1 = 3\forall k_{pv} \). The Sturm sequence of \( \nu_0(\infty, k_{pv}) \) is,

\[ \Psi(\infty, k_{pv}) = \{\alpha_1, \alpha_1, \alpha_3, \alpha_3, \alpha_5, \alpha_5, \alpha_0\}, \]  
(29)

where \( \alpha_1, \alpha_3, \) and \( \alpha_0 \) are functions of system component parameters and inner loop tuning given in [26]. The lower bound on \( k_{pv} \) follows from manipulation of the \( \Psi(\infty, k_{pv}) \) components such that \( p_2 \leq 2 \),

\[ k_{pv} > k_{ic}(L_FR_0 - L_FR_f - k_{pc}(R אכן do not hallucinate.
The stabilizing set \( \Omega(k_{pu}, k_{iv}) \) is defined as the area where
\[
k_{iv} < - \frac{p_1(\omega_1(k_{pu}))}{p_2(\omega_1(k_{pu}))}, k_{pu} \in \Omega(k_{pu}, k_{iv}),
\]
for \( k_{pu} \) lower bounded by the intersection of (30). Inserting \( \omega_1(k_{pu}) \) in (33) upper bounds \( k_{pu} \) as the solution to the polynomial,
\[
\gamma_1 k_{pu}^2 + \gamma_2 k_{pu} + \gamma_3 = 0,
\]
where \( \gamma_1 \) to \( \gamma_3 \) are functions of system parameters given in [26]. The full stabilizing set \( \Omega(k_{pu}, k_{iv}) \) is illustrated in Fig. 5.

If the current control parameters were modified, resulting in a smaller \( \Omega(k_{pu}, k_{iv}) \), unaltered voltage control parameters could provoke under damped oscillations. Furthermore, the combination of a small \( k_{iv} \) and a large \( k_{pu} \) could contribute to the observed phenomena.

V. PROPOSITION II

The PCC voltage is regulated by reactive power from the WT and STATCOM. The PPC provides the voltage reference to the WT control as shown in Fig. 7. The bandwidth of the PPC is low compared to the electrical subsystem, which thus is considered a first order system. In this section, analytical bounds are found for the PPC and the STATCOM using the current control design of Section IV. Combining bounds from sections IV and V constitute the controller parameters for which the system is stable, and the effect of system parameter change, e.g., cable length, is then simulated for all values in the set to estimate the contribution from Proposition II.

\[
\begin{align*}
\frac{\partial Q_t}{\partial u_{pcc}} &= u_{ti} f_q(Z_{t1}, Z_{t2}, 1/Y_t) = Q_{2}^{-1}, u_{ti} = 1 pu, \\
\frac{\partial Q_s}{\partial u_{pcc}} &= u_s f_q(Z_{s1}, Z_{s2}, 1/Y_s) = Q_{3}^{-1}, u_s = 1 pu, \\
\frac{\partial Q_4}{\partial u_{ti}} &= Q_1, \frac{\partial Q_4}{\partial u_{ts}} = Q_4, 
\end{align*}
\]

where \( Q_t \) and \( Q_s \) are the reactive power flows. The sending end, subscript 1, and receiving end, subscript 2, impedance and admittance are \( Z_{1,t} \), \( Z_{s1,t} \), \( Y_s \), and \( Y_t \), and \( f_q(\cdot) \) is a frequency dependent function given in [26].

\[ u_{pcc}^d = u_{pcc}^d - (3S Q_{pcc}^c)/(2n_{wt}Q_{max}), \]

where \( S \) is the desired slope of the droop control, \( n_{wt} \) is the amount of turbines connected, and \( Q_{max} \) is the reactive power capability of one turbine. The reactive power error at the PCC and the output of the WT are [30],
\[
Q_{pcc}^c = (3/2)\left(-u_{pcc}^d i_q\right), Q_{wt} = (3/2)\left(-u_{t1}^d i_q\right).
\]

PI control parameters are found by equating \( Q_{wt} \) to \((1/n_{wt})Q_{pcc}^c\) and adding the integration parameter \( \gamma \),
\[
C_3(s) = k_{pu} + \frac{k_{iv}}{s} = \frac{i_q}{n_{wt}^2} u_{pcc}^d + \frac{\gamma}{s},\]

where the currents are the rated values. Let $T_p$ be the effective rise-time of the inner processes and let the discrete zero order hold plus sampler system in the continuous domain be,
\[
T(s) = (1 - e^{-sT_p})/(T_s s),
\]
then setting $Q_c = Q_1 Q_2$, using a first order Padé time delay approximation and introducing $\alpha = T_s/T_p$ as the response time ratio, the open-loop response is,
\[
u_{pu} = Q_c/(T_s s + (1 + sT_s/2))
\]

The number of distinctive non negative real roots needed to satisfy (7) to guarantee stability is $l \geq 1$ for $n = 2$ and $m = 0$. One non-negative real root for the Sturm sequence given $\nu_{pu}(\omega_0, k_{pu})$ and $\nu_{pu}(\infty, k_{pu})$ is achieved for,
\[
k_{pu} > \frac{1}{Q_c (SQ_4 + 1)} 2Q^2_c (SQ_4 + 1) > 0.
\]

The root is located at,
\[
\omega_{pu}(k_{pu}) = \frac{\sqrt{2}}{\sqrt[\omega_0}{(1 + k_{pu} (SQ_4 + 1))} (\alpha T_v).
\]

Every admissible string for $l = 1$, $\Gamma = \{i_0, i_1\}$, must satisfy,
\[
\text{sign}(\nu_{pu}(0, k_{pu})) (i_0 - i_1) = n - m + 1 = 3,
\]

where sign($\nu_{pu}(0, k_{pu})$) is strictly positive given (46). The only admissible string is $\Gamma_2 = \{1, -1\}$, imposing the non-trivial constraint for $\omega_{pu}(k_{pu})$,
\[
p_1(\omega_{pu}(k_{pu}) + k_{pu} p_2(\omega_{pu}(k_{pu})) < 0,
\]

and by insertion of (47) in (49),
\[
k_{pu} < \frac{1}{\sqrt{2}} \frac{\nu_{pu} + 2}{\nu_{pu}} (SQ_4 + 1) - \frac{1}{\nu_{pu}},
\]

which defines the set $\Omega_H(k_{pu}, k_{pu})$. Inequality (50) shows $a_k \rightarrow 1/T_v$ for $\alpha \rightarrow \infty$ due to increased separation of control and plant bandwidth. An increase of integration gain is needed to guarantee stability as $a_k \rightarrow \infty$ for $\alpha \rightarrow 0$. Increasing the sensitivity to reactive power change, $Q_1$ to $Q_4$, or the droop $S$ decreases the constant factor $b_k$.

### C. Dynamic Reactive Power Compensation

The STATCOM shown in Fig. 8 consists of a reactor and an output filter. A droop plus PI controller regulates the PCC voltage by modifying the STATCOM output current, $i_{so}(s)$, similar to the VSI with an additional reactor. Decoupling the RRF axes and neglecting high frequency filter components, the output current $i_{so}(s)$ and converter voltage $u_{st}(s)$ as inputs and the voltage at the LV side of STATCOM transformer $u_{st}(s)$ as output,
\[
i_{so}(s) = \frac{(n_1 s + n_2) L_{msr} (u_{st}(s) - L_{d} i_{so}(s))}{d_1 s^4 + d_2 s^3 + d_3 s^2 + d_4 s + d_5},
\]

where $d_1$ to $d_5$, $n_1$ and $n_2$ are given in [26]. The control law is,
\[
i_{so}(s) = K_3(s) (w_{st}(s) - u_{st}(s)) \pm \gamma_3 C_{p2} u_{st}(s),
\]

where $K_3(s) = k_{psv} + i_{so}/s$. The Sturm sequence of $\nu_{pu}(0, k_{psv})$ is,
\[
\Psi(\omega_0, k_{psv}) = \{\omega_0, 0, -l_0, 0, l_0, 0, -l_0\},
\]

where the sequence is alternating with $l_0$ as a function of $k_{psv}$ if,
\[
k_{psv} \in \mathbb{R} \left[ \frac{L_{msr} (n_2 d_3 - n_1 d_4) k_{ic} + L_d R_{s} n_2 d_4}{L_{msr} k_{ic} n_2^2} \right] \leq l_0.
\]

The sequence for $\nu_{pu}(\infty, k_{psv})$ is given by,
\[
\Psi(\infty, k_{psv}) = \{\alpha_7, \alpha_7, \alpha_9, \alpha_9, \alpha_10, \alpha_11, 0\},
\]

where $\alpha_7$ through $\alpha_11$ and $\gamma_2$ are given in [26]. For $n = 6$ and $m = 3$, $l \geq 1$ to satisfy (7). This is achieved for,
\[
l_0 < k_{psv} < \gamma_2, \quad k_{ic} > 0, \quad k_{ic} > 0.
\]

The two admissible strings satisfying (9) are $\Gamma_3 = \{1, -1, 1, 1\}$ and $\Gamma_4 = \{-1, -1, 1, -1\}$, imposing constraints,
\[
S_1 : p_1(\omega_2(k_{psv}) + k_{iso p_2}(\omega_2(k_{psv})) > 0,
\]

\[
S_2 : p_1(\omega_3(k_{psv}) + k_{iso p_2}(\omega_3(k_{psv})) < 0,
\]

where $\omega_2(k_{psv})$ and $\omega_3(k_{psv})$ are the isolated roots. The envelope of stability for the STATCOM control, $\Omega_{st}(k_{psv}, k_{icc}) = S_1 \cup S_2$, is shown in Fig. 9.
VI. PARAMETER EFFECT SIMULATION

Sections IV-C, V-B and V-C estimated the control parameters for which each individual system is stable. The effect of control parameters on reactive power oscillations at the PCC is studied by time domain simulation of the entire WPP. Each parameter vector Ψ_i of the joint stabilizing set Ω_M(·) is applied, and the system is subjected to a step in grid voltage. The export cable length is varied from 10% to 300% of nominal, defining the set L_Ω for all Ψ_i.

The dominating frequencies are identified from peaks in the estimated spectral density of the response. The damping of the identified modes are found by time shifting and applying the moving block method [31]. The i'th frequency, maximum peak and damping matrix [f_i, A_i, ζ_i] is sorted descending with respect to maximum peak, and each simulation is represented by two scalars,

\[ f_{m,i} = \sum_{j=1}^{n} (f_{i,j} A_{i,j}) / A_{i,avg}, \]
\[ ζ_{m,i} = \sum_{j=1}^{n} (ζ_{i,j} A_{i,j}) / A_{i,avg}, \]

where \( A_{i,avg} = \sum_{j=1}^{n} (A_{i,j}) \). The results are visualized in a 3D bar plot where the y-axis is the variation of cable length in L_Ω, the x-axis shows the control parameters to be varied, the z-axis is the variation of the parameters within the joint stabilizing set in percent, and the colors represent the damping.

The amplitude weighted damping is shown in Fig. 10. At the edge of the operational envelope, an increase in cable length causes oscillation with low damping at the PCC, while a short cable and fast WT voltage control dampens the oscillations. A longer cable equals a larger impedance, and the PPC integration constant must follow to increase damping.

VII. POSSIBLE CAUSES FOR OBSERVED OSCILLATION

The results of section IV showed that flawed tuning of the WT voltage control alone is able to provoke poorly damped local reactive power oscillations, as illustrated in Fig. 6. Furthermore, an increase in voltage control bandwidth could destabilize the cascade if the current control can not track its reference. As the system employs rate and output limits, this could lead to limit cycles. An insinuation of this being a contributing mechanism is that the oscillations shown in Fig. 2 were attenuated when WTs were disconnected from the PPC. The PPC tuning bounds of section V-B show a correlation between WT voltage control performance and PPC sampling time, and aggressive WT voltage control and neglected group transmission delay in the PPC tuning can combined cause the PPC-WT cascade to show oscillatory behavior.

Time domain simulation of the range of stabilizing WT VSI, PPC and STATCOM control parameters were done in Section VI, and the damping was plotted in Fig. 10. The figure shows that the electrical distance separating the WTs and STATCOM has a large impact on the damping. In line with proposition two, the analytical stability bounds show dependence on grid impedance and are subject to uncertainty.

Settling- and rise time requirements for the reactive power response at the PCC during a voltage change are specified in the grid code. One method to meet the specification is a large PPC integrator gain. The PPC response in turn is dependent on the impedance and, on WPPs with long array-, export- and substation cables, oscillatory behavior can be the result, as we have shown in Section VI. The cable length in the particular is very long for the WPP case referred to in Fig. 2. Fig. 2 shows these observed oscillations compared to a simulation of a WPP with very long cables and a PPC integral gain increased to fulfill the grid code rise time parameter. It is thus plausible that the observed oscillations are caused by the mechanism described and that they can be very poorly damped when having long cables. The grid code specification may therefore be difficult to achieve with the applied strategy for voltage control. Furthermore, if the WT and STATCOM voltage control is tuned according to an aggressive grid code [32], the impact of the system impedance variation with control parameter perturbation shows a possible explanation for the observed phenomena.

VIII. CONCLUSION

The reactive power oscillations encountered when energizing the WPP caused quite a bit of concern as they could not be replicated by simulation software. Identification of problem causes in systems with multiple controllers pose many challenges. Without direct access to the implicated systems, a bottom-up approach was necessary. This paper therefore tied analytical properties of WT and STATCOM control design to a generalized filter setup to assess the performance and disturbance rejection properties.

The voltage control parameter stability envelopes of WT and STATCOM were derived as Hurwitz signatures, as a functions
of control- and system parameters. Based on the results for WT and STATCOM voltage control, stability guidelines for the PPC were proposed to ensure proper cooperation between STATCOM and WT control, considering sampling frequency, droop and network voltage sensitivity. Analytical assessment of the WPP voltage control was shown to be feasible by considering two joint cascade control systems within the complex control topology and model these as a MISO system. The system was simulated over a realistic envelope of electrical impedances and control parameters and it was shown that the oscillatory responses, which were observed, could be reproduced using perturbed parameters in WT voltage control and in the PPC control.

The main-result of the investigation was to show that, assuming a stable combination of WT and STATCOM cascade control, oscillations at the PPC could be caused by a too aggressive PPC setting for the system at hand, according to proposition II. Proposition I was shown to be plausible, but having only a minor contribution to PPC oscillations. Achieving oscillations similar to observed data is not evidence of root cause, but should be seen as proof of possible risks. The methods developed in the paper, should be seen as contributions to mitigate such risk and help avoid similar problems in future WPPs. Finally, the study contributed by demonstrating how the applied voltage control strategy could be modified to decouple the cascaded control systems.

ACKNOWLEDGMENT

The authors would like to thank DONG Energy and the Danish Council for Technology and Innovation for funding the research project.
