First version: June 2008; This version: December 2010

Abstract

This paper proposes a method and a toolkit for solving optimal policy with imperfect commitment in linear quadratic models. As opposed to the existing literature, our method can be employed in medium- and large-scale models typically used in monetary policy. We apply our method to the Smets and Wouters (2007) model, where we show that imperfect commitment has relevant implications for the interest rate setting, the sources of business cycle fluctuations, and welfare. JEL classification: C32, E58, E61.

Keywords: Commitment, Discretion, Linear-Quadratic

1 Introduction

In the modern macroeconomic literature, economic outcomes result from the interactions between policymakers and rational firms and households. A common feature of these models is that economic decisions (e.g., consumption, hours worked, prices) depend on expectations about future policies (e.g., taxes, interest rates, tariffs). As shown by Kydland and Prescott (1977) optimal policy plans in this class of models are subject to time-inconsistency.

The modern literature has taken different approaches to address this problem. One possibility is to assume that policymakers can fully commit – a single optimization is undertaken and the chosen policies are then implemented in all subsequent periods. This approach is known as full-commitment or simply commitment. An alternative, often referred to as discretion or no-commitment, assumes that policymakers cannot commit and that policy plans always need to be time-consistent. Although many types of time-consistent equilibria can be studied, one of the most common approaches is to solve for Markov-perfect equilibria, where policy functions only depend on payoff relevant state variables.

Both the full-commitment and discretion approaches are to some extent unrealistic. Commitment does not match the observation that governments and other institutions have defaulted on past promises. Discretion rules out the possibility that governments achieve the benefits of making and keeping a promise, despite the ex-post incentive to renege. Roberds (1987) developed an approach – recently extended by Schaumburg and Tambalotti (2007) and Debortoli and Nunes (2010a) – which escapes the “commitment vs discretion” dichotomy. Policymakers are endowed with a commitment technology, but with some exogenous and common knowledge probability they may succumb to the temptation to revise their plans. This approach has been labeled quasi-commitment or loose commitment.

Several questions can be addressed with the loose commitment approach. What are the gains of achieving more credibility? How does the possibility of future re-optimizations affect current outcomes and promises? What are the consequences of revising policy plans? How do occasional re-optimizations affect the shock propagation, volatilities, and cross-correlations between relevant variables? To answer these questions and derive the associated positive and normative implications, one must depart from the frameworks of commitment and discretion and consider instead loose commitment.

Nevertheless, given some technical difficulties, the loose commitment ap-
approach has so far been limited to relatively simple and stylized models. The goal of this paper is to overcome this limitation. We propose a simple and relatively general algorithm to solve for the optimal policy plan under loose commitment in linear quadratic frameworks. We show how these types of problems reduce to solving a system of linear difference equations, and do not present any additional challenge with respect to the commitment or discretion cases.

Assuming plans’ revisions to be stochastic events, rather than endogenous decisions, is clearly a simplification analogous in spirit to the Calvo pricing model. While more complex credibility settings can be easily imagined (e.g. an endogenous timing of re-optimizations), such complexity may become prohibitive in medium- and large-scale models. In those type of models, the tractable though simplified approach employed here is particularly valuable.

The paper is related to the literature on optimal monetary policy in linear quadratic frameworks. Solution algorithms for full-commitment, together with a discussion about the computational aspects, have been developed by Currie and Levine (1993) and Söderlind (1999), among others. Methods to solve for (Markov-perfect) time-consistent equilibria are described in Backus and Drifill (1985), Söderlind (1999), and Dennis (2007). The main contribution of the paper is to extend these methodologies to address problems under loose commitment. To illustrate the benefits of our approach, the methodology is then applied to analyze the effects of commitment in the medium-scale model of Smets and Wouters (2007), which has arguably become one of the benchmark models in the dynamic stochastic general equilibrium literature.

The paper continues as follows. In section 2 we introduce the general formulation of the model. In section 3 we study the optimal policy problem and describe the solution algorithm. Section 4 discusses the role of commitment in the Smets and Wouters (2007) model and section 5 concludes. We provide as supplementary material a collection of codes and documentation that implement our algorithm in a variety of models.

1See also Klein et al. (2005) and Judd (2004) for more general non-linear problems.
2We have also tested our methodology with bigger models used for monetary policy analysis, such as the Norwegian Economy Model (NEMO) of the Norges Bank.
2 General form of the models

Consider a general linear model, whose structural equations can be cast in the form

\[ A_{-1}y_{t-1} + A_0y_t + A_1y_{t+1} + Bv_t = 0, \quad \forall t \]  

(1)

where \( y_t \) indicates a vector of endogenous variables and \( v_t \) is a vector of serially uncorrelated exogenous disturbances with zero mean and \( Ev_tv_t' = \Sigma_v \). As it is well known, models with more lags and leads, lagged expectations, constants, and serially correlated shocks can be accommodated into this formulation by expanding the \( y_t \) vector. The policymaker is assumed to have a quadratic loss function

\[ \sum_{t=0}^{\infty} \beta^t y_t'Wy_t \]  

(2)

A purely quadratic objective function is consistent with a second-order Taylor expansion of general time-separable utility functions around an efficient steady-state (see e.g. Woodford (2003a)). Stochastic targets and preference shocks can also be incorporated by suitably expanding the vector \( y_t \).

3 Optimal policy under Loose Commitment

In a loose commitment setting it is assumed that policymakers do have access to a commitment technology, but at the same time they occasionally revise their plans. More formally, suppose that the occurrence of a re-optimization is driven by a two-state Markov stochastic process

\[ \eta_t = \begin{cases} 1 & \text{with Prob. } \gamma \\ 0 & \text{with Prob. } 1 - \gamma \end{cases} \]  

(3)

In the presence of steady-state distortions, a purely quadratic objective can be obtained using a simple linear combinations of the structural equations approximated to a second-order. However, as shown by Debortoli and Nunes (2006), this requires imposing the so-called “timeless perspective assumption”, which contrasts with the loose commitment settings considered in this paper. For an alternative approach, see Schmitt-Grohe and Uribe (2005).

In the companion code, models with more lags, leads, constants etc., are automatically transformed to be consistent with the formulation in equations (1) and (2).
At any given point in time if $\eta_t = 1$, previous commitments are honored. This event occur with probability $0 \leq \gamma \leq 1$. Instead, if $\eta_t = 0$ the planner makes a new plan. This formulation nests both the full-commitment and discretion approaches as limiting cases where $\gamma = 1$ and $\gamma = 0$, respectively. More importantly, this formulation also spans the continuum between those two extremes.

Considering stochastic re-optimizations is a necessary simplification to address large scale models. Such an assumption also seems justified if the timing of plans revisions is uncorrelated with the state of the economy. Possible candidates for such events are changes in the dominating view within a central bank due to time-varying composition of its decision-making committee or varying intensity of outside pressures by politicians and the financial industry.\textsuperscript{5} Alternatively, our approach can be interpreted as the reduced form of a model in which commitment to a policy is sustained by the threat of a punishment in case of re-optimization. If the punishment requires a priori coordination among private agents and in some random periods cannot be implemented, then such a model may bear similarities with our approach.\textsuperscript{6}

Following Schaumburg and Tambalotti (2007) and Debortoli and Nunes (2010a), the policymaker’s problem can be written as

$$y'_{-1}Py_{-1} + d = \min_{\{y_t\}_{t=0}^{\infty}} E_{-1} \sum_{t=0}^{\infty} (\beta \gamma)^t [y_t'Wy_t + \beta (1 - \gamma) (y_t'Py_t + d)]$$

$$s.t. \quad A_{-1}y_{-1} + A_0y_t + \gamma A_1E_t y_{t+1} + (1 - \gamma) A_1E_t y'_{t+1} + Bv_t = 0. \quad \forall t \geq 0$$

The objective function is given by an infinite sum discounted at the rate $\beta \gamma$, summarizing the history in which re-optimizations never occur. Each term

\textsuperscript{5}In the case of the United States, the reserve bank presidents serve one-year terms as voting members of the FOMC on a rotating basis, except for the president of the New York Fed. Furthermore, substantial turnover among the reserve bank presidents and the members of the Board of Governors arises due to retirement and outside options. With the (up to) seven members of the Board of Governors being nominated by the U.S. President and confirmed by the U.S. Senate, the composition of views in the FOMC may be affected by the views of the political party in power at the time of the appointment. Chappell et al. (1993) and Berger and Woitek (2005) find evidence of such effects in the U.S. and Germany, respectively.

\textsuperscript{6}Such a framework would build on the seminal contributions of Chari and Kehoe (1990), and Kehoe and Levine (1993). A related approach using a model of imperfect information is described in Sleet (2001). Most of these frameworks model the private sector as a representative household therefore avoiding the coordination problem.
in the summation is composed by two parts. The first part is the period loss function. The second part indicates the value the policymaker obtains if a re-optimization occurs in the next period.

The policymaker faces a sequence of constraints, where in any period $t$ expectations of future variables are an average between two terms. The first term $(y_{t+1})$, with weight $\gamma$, relates to the allocations prevailing when current plans are honored. The second term $y^r_{t+1}$, with weight $(1-\gamma)$, refers to the choices made in period $t+1$ if a re-optimization occurs (i.e. if $\eta_{t+1} = 0$). Analogously to the Markov-perfect literature, we assume that expectations about choices following a re-optimization only depend on state-variables.

$$E_t y^r_{t+1} = \tilde{H} y_t.$$  \hfill (5)

The policymaker cannot decide directly on the allocations implemented if a re-optimization occurs and therefore the matrix $\tilde{H}$ is taken as given.

For any $\tilde{H}$, the policymaker problem can be solved using recursive methods. We follow the approach of Kydland and Prescott (1980) and Marcet and Marimon (2009), and write the Lagrangean associated with the policymaker’s problem

$$\mathcal{L} = E_{-1} \sum_{t=0}^{\infty} (\beta \gamma)^t \left\{ y_t^t [W + (1 - \gamma) \beta P] y_t + \lambda_{t-1}^{-1} A_1 y_t + \lambda_{t-1}^{-1} A_1 \tilde{H} y_t + B v_t \right\} \quad \text{(6)}$$

$$\lambda_{-1} = 0$$

$\tilde{H}, y_{-1}$ given.

This Lagrangean can be written recursively after expanding the state of the economy to include the Lagrange multiplier vector $\lambda_{t-1}$ as co-states. The solution to the problem is then characterized by a time-invariant policy function

$$\begin{bmatrix} y_t \\ \lambda_t \end{bmatrix} = \begin{bmatrix} H_{yy} & H_{y\lambda} \\ H_{\lambda y} & H_{\lambda\lambda} \end{bmatrix} \begin{bmatrix} y_{t-1} \\ \lambda_{t-1} \end{bmatrix} + \begin{bmatrix} G_y \\ G_{\lambda} \end{bmatrix} v_t, \quad \text{(7)}$$

where the matrices $H$ and $G$ depend on the unknown matrix $\tilde{H}$.

When a re-optimization occurs in a given period $t$, the vector $\lambda_{t-1}$ must be reset to zero. This result has been formally proved by Debortoli and Nunes (2010a). According to the formulation in (6), this result has an intuitive
interpretation. A re-optimization implies that all the past promises regarding current and future variables are no longer binding.

According to equation (7) and setting $\lambda_{t-1} = 0$, it follows that $y^*_t = H_{yy}y_{t-1} + G_y v_t$. Moving this equation forward one period and taking expectations, one obtains $E_t y^*_{t+1} = H_{yy} y_t$. For this expression to be consistent with equation (5), it must be that in a rational expectations equilibrium

$$H_{yy} = \tilde{H}. \quad (8)$$

Given our formulation, the optimal policy under loose commitment can be found as the solution of a fixed point problem in the matrix $H$. In what follows we propose an algorithm to solve for that fixed point.

### 3.1 Solution algorithm

We start by writing the first-order conditions of the Lagrangean (6):

$$\frac{\partial L}{\partial \lambda_t} = [A_0 + (1 - \gamma) A_1 H_{yy}] y_t + \gamma A_1 E_t y_{t+1} + A_{-1} y_{t-1} + B v_t = 0 \quad (9)$$

$$\frac{\partial L}{\partial y_t} = 2 W y_t + \beta (1 - \gamma) A'_{-1} E_t \lambda_{t+1} + (A_0 + (1 - \gamma) A_1 H_{yy})' \lambda_t + I_\gamma \beta^{-1} A'_{-1} E_t \lambda_{t-1} = 0. \quad (10)$$

The vector equation (9) corresponds to the structural equation (1), where we have used equations (5) and (8) to substitute for the term $E_t y^*_{t+1}$. As a result, the unknown matrix $H_{yy}$ enters equation (9). That matrix also enters equation (10), reflecting that $y_t$ can be used to affect the expectations of $y^*_{t+1}$. The term $\lambda_{t+1}$ in equation (10) constitutes the derivative of the value function w.r.t. $y_t$. This derivative can be obtained using the envelope condition

$$\frac{\partial y'_t P y_t}{\partial y_t} = 2 P y_t = A'_{-1} E_t \lambda^*_{t+1}. \quad (11)$$

Finally, the term $I_\gamma$ in equation (10) is an indicator function

$$I_\gamma = \begin{cases} 
0, & \text{if } \gamma = 0 \\
1, & \text{otherwise}
\end{cases}$$

and is used for convenience so that equation (10) is also valid under discretion ($\gamma = 0$), where the term $\beta^{-1} A'_{-1} \lambda_{t-1}$ would not appear.\footnote{The indicator function is only needed because when deriving equation (10) we have divided all terms by $(\beta \gamma)^t$, which can be done only if $\gamma \neq 0$.}
There are many methods to solve linear rational expectation systems like (9)-(10), and standard routines are widely available (e.g. Sims (2002), Collard and Juillard (2001)). Our computational implementation is based on the method of undetermined coefficients.

For a given guess of the matrix $H$, the law of motion (7) can be used to compute the expectations terms

$$E_t y_{t+1} = H_{yy} y_t + H_{y\lambda} \lambda_t \quad (12)$$
$$E_t \lambda_{t+1} = H_{\lambda y} y_t + H_{\lambda \lambda} \lambda_t \quad (13)$$
$$E_t \lambda_{t+1} = H_{\lambda y} y_t \quad (14)$$

where the last equation follows from resetting the Lagrange multiplier $\lambda_t$ to zero due to the re-optimization at $t + 1$. Substituting these formulas into (9)-(10) one obtains

$$\Gamma_0 \begin{bmatrix} y_t \\ \lambda_t \end{bmatrix} + \Gamma_1 \begin{bmatrix} y_{t-1} \\ \lambda_{t-1} \end{bmatrix} + \Gamma_v v_t = 0, \quad (15)$$

with

$$\Gamma_0 \equiv \begin{bmatrix} A_0 + A_1 H_{yy} & \gamma A_1 H_{y\lambda} \\ 2W + \beta A'_{\lambda} H_{\lambda y} & A'_0 + (1 - \gamma) H_{yy} A'_1 + \beta \gamma A'_{\lambda} H_{\lambda \lambda} \end{bmatrix}$$
$$\Gamma_1 \equiv \begin{bmatrix} A_{-1} & 0 \\ 0 & \beta^{-1} I_{\gamma} A'_1 \end{bmatrix}, \quad \Gamma_v \equiv \begin{bmatrix} B \\ 0 \end{bmatrix}.$$ 

The resulting law of motion is

$$\begin{bmatrix} y_t \\ \lambda_t \end{bmatrix} = -\Gamma_0^{-1} \Gamma_1 \begin{bmatrix} y_{t-1} \\ \lambda_{t-1} \end{bmatrix} - \Gamma_0^{-1} \Gamma_v v_t, \quad (16)$$

where we are assuming the matrix $\Gamma_0$ to be non-singular.

The final step consists in verifying that this law of motion coincides with the initial guess, i.e. $H = -\Gamma_0^{-1} \Gamma_1$. If not, the guess-and-verify procedure is repeated until convergence. In summary, the algorithm proceeds as follows:

1. Using a guess $H_{\text{guess}}$, form $\Gamma_0$ and $\Gamma_1$.

2. Compute $H = -\Gamma_0^{-1} \Gamma_1$.

3. Check if $\|H - H_{\text{guess}}\| < \xi$, where $\|\cdot\|$ is a distance measure and $\xi > 0$. If the guess and the solution have converged, proceed to step 4. Otherwise, update the guess as $H_{\text{guess}} = H$ and repeat steps 1-3 until convergence.
4. Finally, form $\Gamma_v$ and compute $G = -\Gamma_0^{-1}\Gamma_v$.

Clearly, there are many alternative algorithms to the one proposed. For example, for a given $H$ the system of equations (9)-(10) could be solved using a generalized Schur decomposition as in Blanchard and Kahn (1980) or solving a quadratic matrix equation as in Uhlig (1995). For this reason, the non-singularity of the matrix $\Gamma_0$ is not essential. Also, the solution of the fixed point problem on the matrix $H$ could be performed using a Newton-type method. Nevertheless, the procedure described above proved to be more efficient from a computational viewpoint.

The main message of our analysis is that solving for an optimal policy problem under loose commitment only requires solving a fixed point problem, which in a linear-quadratic framework is as simple as solving a system of linear equations. In addition, a loose commitment approach nests the full-commitment and discretion cases. In this respect, Blake and Kirsanova (2010) show that under discretion, some linear-quadratic models may display multiple equilibria. In those cases, and depending on the initial guess, our algorithm may then converge to different discretionary equilibria. However, our loose commitment approach, by allowing gradual intermediate steps from full-commitment to discretion, may be viewed as a selection device among those multiple equilibria.

3.2 Simulations and impulse responses

Once the matrices $H$ and $G$ have been obtained, it is straightforward to simulate the model for different realizations of the shocks and compute second moments and impulse response functions. The peculiarity of the loose commitment setting is that a history of the shock driving the re-optimizations $(\eta_t)$ should also be specified. Whenever $\eta_t = 0$, the Lagrange multiplier $\lambda_{t-1}$ needs to be reset to zero. In other words, for given initial conditions $y_{t-1}$, $\lambda_{t-1}$, and histories of the shocks $\{v_t, \eta_t\}_{t=0}^T$, the model simulation follows the formula

\[
\begin{bmatrix}
y_t \\
\lambda_t
\end{bmatrix} = H \begin{bmatrix}
y_{t-1} \\
\eta_t \lambda_{t-1}
\end{bmatrix} + G v_t.
\]

---

8The authors also propose a way to detect and compute the multiple equilibria, which we view as a complement to our analysis.

9Dennis and Kirsanova (2010) propose alternative selection devices based on the concepts of robustness and learnability.
3.3 Welfare

For any initial condition \([y_{t-1} \lambda_{t-1}]\) the welfare measure, unconditional on the first realization of \(v_0\), is given by

\[
\begin{bmatrix}
  y_{t-1} \\
  \lambda_{t-1} \\
  v_t
\end{bmatrix}
\begin{bmatrix}
  y_{t-1} \\
  \lambda_{t-1} \\
  v_t
\end{bmatrix}
+ d. \tag{17}
\]

The matrix \(\hat{P}\) can be obtained taking the derivative of the recursive formulation of the Lagrangean (6), thus obtaining

\[
\hat{P} = \frac{1}{2} \begin{bmatrix}
  0 & A'_{t-1} \\
  \beta^{-1} A_1 & 0
\end{bmatrix} H. \tag{18}
\]

Notice that in the most relevant case with \(\lambda_{t-1} = 0\) the only relevant term would be the upper left block of \(\hat{P}\), which equals \(A'_{t-1} H_y\).

The constant \(d\) is instead given by

\[
d = \frac{1}{1 - \beta} tr \left( \Sigma_v \left( G' \tilde{V} G + G' \begin{bmatrix} 0 \\ B \end{bmatrix} \right) \right) \tag{19}
\]

with

\[
\tilde{V} = \left( \begin{bmatrix}
  A_0 + (1 - \gamma) A_1 H_yy & 0 \\
  0 & 0
\end{bmatrix} + \beta (1 - \gamma) \begin{bmatrix}
  A'_{t-1} H_y 0 \\
  0 0
\end{bmatrix} + \beta \gamma \hat{P} \right). \tag{10}
\]

Similarly, we can compute a measure of welfare, conditional on the first realization of the shock, which is defined as follows:

\[
\begin{bmatrix}
  y_{t-1} \\
  \lambda_{t-1} \\
  v_t
\end{bmatrix}
\begin{bmatrix}
  y_{t-1} \\
  \lambda_{t-1} \\
  v_t
\end{bmatrix}
+ \tilde{d} = y_t' W y_t 
\]

\[
+ \beta \gamma E_t \left( \begin{bmatrix}
  y_t \\
  \lambda_t \\
  v_{t+1}
\end{bmatrix}
\begin{bmatrix}
  y_t \\
  \lambda_t \\
  v_{t+1}
\end{bmatrix}
+ \tilde{d} \right) \]

\[
+ \beta (1 - \gamma) E_t \left( \begin{bmatrix}
  y_t \\
  0 \\
  v_{t+1}
\end{bmatrix}
\begin{bmatrix}
  y_t \\
  0 \\
  v_{t+1}
\end{bmatrix}
+ \tilde{d} \right) 
\]

\footnote{The associated derivations, which follow the steps in Ljungqvist and Sargent (2004) (Ch. 5), are omitted for brevity and are available upon request.}
By definition of conditional welfare, it must be that:

$$E_t \left( \begin{bmatrix} y_t & \lambda_t \\ v_{t+1} & \end{bmatrix} ' \tilde{P} \begin{bmatrix} y_t \\ \lambda_t \\ v_{t+1} \end{bmatrix} \right) + \tilde{d} = \left( \begin{bmatrix} y_t ' \tilde{P} [y_t] + d \right),$$

so that equation (20) can be rewritten as

$$\begin{bmatrix} y_{t-1} \\ \lambda_{t-1} \\ v_t \end{bmatrix} ' \tilde{P} \begin{bmatrix} y_{t-1} \\ \lambda_{t-1} \\ v_t \end{bmatrix} + \tilde{d} =$$

$$\left( H \begin{bmatrix} y_{t-1} \\ \lambda_{t-1} \end{bmatrix} + G v_t \right) ' \tilde{V} \left( H \begin{bmatrix} y_{t-1} \\ \lambda_{t-1} \end{bmatrix} + G v_t \right) +$$

$$\left( H \begin{bmatrix} y_{t-1} \\ \lambda_{t-1} \end{bmatrix} + G v_t \right) ' \left( \begin{bmatrix} 0 & \beta^{-1} A_1 ' \\ A_1 & 0 \end{bmatrix} \begin{bmatrix} y_{t-1} \\ \lambda_{t-1} \end{bmatrix} + \begin{bmatrix} 0 \\ B \end{bmatrix} v_t \right) + \beta d.$$

We can thus obtain the conditional welfare, for any given initial condition, by just evaluating the right-hand side of this last expression.

In these derivations we have computed welfare using the recursive formulation of the Lagrangean (6). As mentioned earlier, that formulation is equivalent to the original problem (4) only after imposing the initial condition $\lambda_{-1} = 0$. If one wants to evaluate the welfare according to the original formulation of equation (2), but for a different value of $\lambda_{-1}$, one needs to subtract $\lambda_{-1} \beta^{-1} A_1 E_{-1} y_0$ and $\lambda_{-1} \beta^{-1} A_1 y_0$ to equations (17) and (22), respectively.\(^{11}\)

4 Application: a medium-scale closed economy model

In this section, we apply our methodology to the Smets and Wouters (2007) model. Needless to say, our purpose is neither to match business cycle properties nor to test the empirical plausibility of alternative commitment assumptions. We instead focus on examining the role of commitment in this benchmark medium-scale model.

The model includes nominal frictions in the form of sticky price and wage settings allowing for backward inflation indexation.\(^{12}\) It also features real

---

\(^{11}\)Our sample codes incorporate these correction terms.

\(^{12}\)Sticky nominal wages and prices follow the formulations of Erceg et al. (2000) and Yun (1996).
rigidities – habit formation in consumption, investment adjustment costs, variable capital utilization, and fixed costs in production. The dynamics are driven by six orthogonal shocks: total factor productivity, two shocks affecting the intertemporal margin (risk premium and investment-specific technology shocks), two shocks affecting the intratemporal margin (wage and price-markup shocks), and an exogenous government spending shock. The model equations are omitted here for brevity and all parameters are calibrated to the posterior mode as reported in Smets and Wouters (2007).

Unlike Smets and Wouters (2007), we do not consider a specific interest rate rule nor the associated monetary policy shock. Instead, we assume that the central bank solves an optimal policy problem. By doing so, we exemplify how the degree of commitment and the re-optimization shocks affect the behavior of the central bank. We are not dismissing interest rate rules either from a normative or a positive perspective. In fact, it is widely known that optimal policy plans can be implemented in a variety of ways including targeting rules and instrument rules, of which interest rate rules are a subcase.

To the best of our knowledge, the utility-based welfare criterion for the Smets and Wouters (2007) model has not been derived, and doing so is beyond the scope of this paper. Instead, we explore the implications of considering two alternative purely quadratic loss functions commonly used in the literature. The benchmark formulation is given by

$$U^b_t = w_\pi \pi_t^2 + w_y y_t^2 + w_b (i_t - i_{t-1})^2,$$  

(23)

while the alternative specifications takes the form

$$U^a_t = w_\pi \pi_t^2 + w_y y_t^2 + w_a i_t^2.$$  

(24)

Following Woodford (2003b), we set the parameters $w_\pi = 1$, $w_y = 0.003$, $w_b^b = 0.0176$, and $w_a^a = 0.0048$. The plausibility of these formulations and of the corresponding calibration is discussed in the following sections, where we analyze the importance of commitment from different perspectives.

4.1 What are the gains from commitment?

In Figure 1, we plot the conditional welfare gains obtained for different levels of credibility. The figure standardizes the gains of commitment by

\footnote{Whereas we consider the conditional welfare gains, the figure is similar if we do not condition on the realization of the shocks.}
the total gains obtained from discretion to full-commitment. Therefore, any affine transformation of the central bank’s objective function would leave Figure 1 unchanged.

As expected, higher credibility leads to higher welfare. More importantly, the figure suggests that if a central bank has low credibility to start with, a partial enhancement of its credibility will not deliver much of the welfare gains that credibility can potentially offer. Similarly, a central bank with high credibility should be especially cautious. It will face severe welfare losses if its credibility is deemed to have been minimally affected. These results contrast with those obtained by Schaumburg and Tambalotti (2007) using a more stylized monetary policy model.

Figure 1: Welfare

Notes: The figure plots the relative welfare gains of increasing credibility from full discretion to a degree of commitment \( \gamma \): \( (V_\gamma - V_{\gamma=0})/(V_{\gamma=1} - V_{\gamma=0}) \). The panel on the left corresponds to the benchmark objective function, whereas the right panel corresponds to the alternative welfare function with the interest rate level. The welfare measure corresponds to conditional welfare and the results are robust to unconditioning on the shocks.

Credibility may also affect the relative contribution of inflation and output-gap volatilities to the overall welfare loss. A higher credibility level translates into better management of the policy trade-offs because forward guidance is

---

14 This result is formally proven in Debortoli and Nunes (2010a).

15 The result is instead consistent with those of Debortoli and Nunes (2010a). Also, as discussed there, the shape of the relative welfare gains change with the commitment metric. Here, we are considering and comparing results in the literature along the probability of commitment metric.
more effective as a policy tool. Therefore one might conjecture that higher credibility would reduce the volatilities of all welfare relevant variables. Figure 2 exemplifies that such a conjecture does not always hold. The figure shows that for a given relative weight in the objective function, a loss in credibility leads to a rise in inflation volatility but a reduction in output-gap volatility. The reason is that stabilizing inflation is the most important welfare objective. A central bank with high credibility can achieve a higher welfare by promising to stabilize inflation even if doing so implies more output-gap volatility.

**Figure 2: Credibility and volatility**

Notes: the figure plots the volatilities of inflation, output-gap, and interest rate for different credibility levels. The left and right panel change the weight on inflation and output-gap, respectively. The two panels plot several weights from half to double of the benchmark value. The solid and dashed lines consider the probability of commitment to be 0.5 and 1, respectively.

Figure 2 also discriminates among the points in the policy frontiers associated with doubling or halving \( w_\pi \) or \( w_y \) relative to the baseline calibration. Doubling or halving the mentioned parameters leads to changes that are not extreme in magnitude. Thus, results are not overly sensitive to the calibration of the objective function. Also, the finding that a loss in credibility increases inflation volatility but reduces output-gap volatility holds for those extreme calibrations as well.
4.2 Loose commitment and simple interest rate rules

The optimal policy under loose commitment can be implemented through targeting rules or through an appropriately defined interest rate rule. In DSGE monetary policy models it is instead common to adopt simple reduced-form interest rate rules to describe the central bank’s behavior. Clearly, such behavior is affected by the degree of commitment $\gamma$. An open question is to see how changes in $\gamma$ are captured by the parameters of a simple rule. To address this question, we perform a Monte-Carlo exercise taking our model as the pseudo-true data generating process but estimating the interest rate rule

$$i_t = \phi_i i_{t-1} + \phi_\pi \pi_t + \phi_y y_t + \epsilon_t$$

where $\epsilon_t$ is assumed to be i.i.d. and normally distributed.

Table 1 presents the regression results. The coefficient estimates are similar to those found in the literature using actual data. In most cases, the coefficient on output-gap is small (and in some cases not significant), the coefficient on inflation is plausible, and there is a considerable degree of interest rate smoothing. Most of the motive for interest-rate smoothing comes from commitment. Commitment implies that past policies matter for current allocations, thus introducing history dependence. As a result, when commitment is high, the estimated values of $\phi_i$ are high even under the alternative loss function, where per se there is no interest-rate smoothing motive. Overall, the coefficient $\phi_i$ is more plausible for relatively loose commitment settings rather than with full-commitment.

Simple interest rate rules have been widely adopted to study the central bank behavior across different periods of time. In that respect, our exercise shows that a change in the interest rate parameters ($\phi_i, \phi_\pi, \phi_y$) should not be necessarily interpreted as a change in the central bank’s preferences. Even if preferences remain unaltered, the reduced form interest rate parameters may change because of a loss of credibility.

---

16 Evans and Honkapohja (2003) discuss how interest rate rules can implement the optimal policy plan, while targeting rules are discussed by Giannoni and Woodford (2010) in a general framework and by Debortoli and Nunes (2010b) in a loose commitment setting.

17 For comparability with some studies the coefficient on inflation and output-gap should be adjusted as $\phi_\pi/(1 - \phi_i)$ and $\phi_y/(1 - \phi_i)$, respectively.

18 For example, an optimal policy plan under full-commitment displays history dependence even when all the disturbances are i.i.d. and in the absence of natural state variables. See e.g. Galí (2008, ch. 5).

Notes: The table displays the coefficients and standard deviations corresponding to estimating equation (25) in the original model. The Monte-Carlo exercise is comprised of 1000 estimations of 200 periods each (roughly corresponding to the size of actual samples). The average standard deviations across simulations are reported in parenthesis. The last row displays the $R^2$. The panel on the left and the right correspond to the benchmark and alternative welfare functions, respectively.

In general the simple rule (25) captures fairly well the interest rate behavior, as signaled by the high value of the $R^2$. The $R^2$ is plausible but lower at intermediate degrees of commitment. The reason is that re-optimizations imply a non-linear change in the policy setting that the linear regression is not capturing well. The re-optimization uncertainty vanishes with full-commitment or discretion, and therefore those two cases can be better described by a linear rule. Also, the $R^2$ is lower for the alternative specification of the loss function. In that case, the absence of an interest rate smoothing motive in the objective function causes the interest rate to change more abruptly when re-optimizations occur. This suggests that our benchmark loss function is more consistent with available estimates of the central bank behavior.

### 4.3 Business cycle properties under loose commitment

We now analyze the effects of commitment on business cycle properties. Impulse responses to different shocks are reported in Figures 3-5. The probability of commitment is set to $\gamma = .9$, implying that policy re-optimizations occur on average every 10 quarters. The solid line considers the specific history where re-optimizations do not occur over the reported horizon ($\eta_t = 1, \forall t$).
On impact, the sign of the responses does not change with the commitment assumption. However, for each of the shocks considered, after about 6 quarters the response of the nominal interest rate does not lie between full-commitment (dashed line) and discretion (dash-dotted line). These differences arise because of the uncertainty about future re-optimizations, a feature unique to loose commitment settings.

For example, the interest rate response to a positive wage markup shock shown in Figure 3 peaks after about 10 quarters – as opposed to a negligible response at a similar horizon both under full-commitment and discretion. In turn, the output-gap response is more prolonged, while both price and wage inflation are close to the values prevailing under commitment. Intuitively, the promise of a deeper and longer recession dampens inflation expectations and helps achieve a higher welfare. When the central bank reoptimizes (line with crosses), it reneges upon past promises. It then reduces the interest rate, causing inflation to increase and the output-gap to decrease. The bottom right panel shows that the welfare gain of reoptimizing in a given quarter – a measure of the time-inconsistency at each moment in time – is maximum after roughly 9 quarters. The central bank is fulfilling the promise of a deep recession, which becomes especially costly at that time because inflation is already below target and the output-gap is at its lowest level.

Similar reasoning also applies to productivity and government spending shocks. In response to the latter shocks – as well as to other demand-type shocks – the output-gap and the two measures of inflation are well stabilized. This occurs regardless of the degree of commitment, and as long as the central bank sets its policy optimally. This suggests that commitment would not be very important if these shocks were the main sources of business cycle fluctuations. Also, the time-inconsistency problem, measured by the gains from re-optimizations (bottom right panel), is much smaller in response to technology and government spending shocks than in response to wage markup shocks.

Table 2 shows how commitment affects the second moments for some relevant variables. The correlation of output with the two measures of inflation is positive under full-commitment, it becomes negative at intermediate de-

19The responses to other shocks also present the same features and are omitted for brevity, but are available upon request.

20However, this result is not obvious in the current model. The presence of both price and wage rigidities implies a trade-off between inflation and output stabilization, and thus a scope for commitment, even in response to demand and technology shocks.
Figure 3: Impulse responses to a wage markup shock

Notes: The figure plots the impulse responses to a one standard deviation shock, under different commitment settings. The solid line refers to a particular history where the probability of commitment $\gamma = .9$ and re-optimizations do not occur ($\eta_t = 1, \forall t$). The line with crosses refers to a particular history where the probability of commitment $\gamma = .9$ and a single re-optimization occurs after 10 quarters ($\eta_0 = 0, \eta_t = 1, \forall t \neq 10$). For any quarter, the gains from re-optimization are computed as the welfare difference between keeping the announced plan vs re-optimizing in that particular quarter.
Figure 4: Impulse responses to a productivity shock

Notes: The figure plots the impulse responses to a one standard deviation shock, under different commitment settings. The solid line refers to a particular history where the probability of commitment $\gamma = .9$ and re-optimizations do not occur ($\eta_t = 1, \forall t$). The line with crosses refers to a particular history where the probability of commitment $\gamma = .9$ and a single re-optimization occurs after 10 quarters ($\eta_1 = 0, \eta_t = 1, \forall t \neq 10$). For any quarter, the gains from re-optimization are computed as the welfare difference between keeping the announced plan vs re-optimizing in that particular quarter.
Figure 5: Impulse responses to a government spending shock

Notes: The figure plots the impulse responses to a one standard deviation shock, under different commitment settings. The solid line refers to a particular history where the probability of commitment $\gamma = .9$ and re-optimizations do not occur ($\eta_t = 1, \forall t$). The line with crosses refers to a particular history where the probability of commitment $\gamma = .9$ and a single re-optimization occurs after 10 quarters ($\eta_0 = 0, \eta_t = 1, \forall t \neq 10$). For any quarter, the gains from re-optimization are computed as the welfare difference between keeping the announced plan vs reoptimizing in that particular quarter.
degrees of commitment. The reason is that under full-commitment output and inflation are positively correlated not only conditionally on demand shocks, but also conditionally on technology and markup shocks. In response to the latter shocks output and inflation move in opposite directions on impact, but after about 5 quarters they comove. Instead, with loose commitment, especially if a re-optimization has occurred, inflation and output move in opposite directions for a longer horizon. As a result, the correlation between inflation and output conditional on non-demand shocks, as well as the unconditional counterpart, changes sign with even a small departure from the full-commitment assumption.  

Even though it is beyond the scope of this paper to estimate the model and the degree of credibility, the loose commitment model matches some key moments relatively well. Table 2 shows that in the data the correlation between output and price inflation is mildly negative, whereas the correlation between output and wage inflation is mildly positive – a feature that the loose commitment model with $\gamma = 0.9$ matches quite well. In addition, the relative volatility of interest rates is also more plausible with limited commitment settings.

Finally, loose commitment changes the relative contribution of alternative shocks to business cycle fluctuations, as summarized in Figure 6. This pattern is mostly evident for interest rate fluctuations. Under full-commitment about 55% of the fluctuations can be attributed to demand shocks. A small loss of credibility ($\gamma = .9$) is enough for this proportion to drop dramatically to about 16%. The contribution of wage and price markup shocks increases from 20% to 70%. The reason is that the interest-rate response to a demand shock does not change much with the degree of commitment. Instead, in response to markup shocks the interest rate barely responds under commitment, while it increases and remains high for a long period in limited commitment settings. For almost all the other variables, when commitment is lower, price markup shocks lose importance and wage markup shocks become more relevant. Hence, the variance decompositions and the earlier plots measuring time-inconsistency suggest that commitment is particularly important to stabilize wage markup shocks.

In summary, loose commitment has important effects on price and wage inflation dynamics, and nominal interest rates – the main variables for which

Notes: The table displays several statistics for the output-gap, inflation, wage inflation, and the interest rate. The model statistics are computed with 1000 simulations of 200 periods each. The sample regarding the real data goes from 1970:Q1 until 2008:Q3, where the latest data is determined by the beginning of the zero lower bound period. The output-gap data corresponds to the CBO measure.

the central bank is responsible. The impulse responses to different shocks, as well as the interest rate volatility, is not necessarily in between full-commitment and discretion. Finally, small departures from full-commitment change the sign of the correlation between output and inflation. In addition, the relative contribution of wage markup shocks to business cycle fluctuations increases dramatically, especially for interest rates and inflation.

5 Conclusions

Imperfect commitment settings overcome the dichotomy between full-commitment and discretion. In practice, policymakers have some degree of commitment that is not perfect – in some cases they keep a previously formulated policy plan whereas in other cases they reformulate those plans. Recent proposals of imperfect commitment settings were restricted to relatively simple and stylized models.

The contribution of this paper is to propose a method and a toolkit that extends the applicability of loose commitment to medium- and large-
Figure 6: Variance decomposition

Notes: The figure displays the contribution of different shocks to the variance of our variables, under different commitment scenarios. For convenience, risk premium, investment specific, and government spending shocks have been grouped as “demand” shocks. The model statistics are computed with 1000 simulations of 200 periods each.

scale linear quadratic models. We exemplified the method in the Smets and Wouters (2007) model, where we posed a variety of questions that our method can address and would remain otherwise unanswered.

This work can be fruitfully extended in several ways. Considering alternative intermediate credibility settings is certainly desirable, but technical and computational complexity may become prohibitive to address the medium- and large-scale models considered here. Also, our methodology could constitute a useful step towards analyzing the plausibility of alternative commitment settings through an appropriate estimation exercise. We plan to pursue these projects in the near future.
