Impact of sample quality on CPTU correlations in clay—example from the Rakkestad clay

Norwegian Geotechnical Institute (NGI), Oslo, Norway

ABSTRACT: As part of the zoning plan for the new 30 km long highway, E16, from Nybakk to Slomarka, an extensive laboratory and field testing campaign was conducted by NGI. The deposit along the highway is a normally to slightly overconsolidated clay with a water content in the range of 30–45% and a plasticity index ranging between 7–25%. 72 mm diameter piston samples at 70 localities were taken and CPTUs were carried out at over 120 locations. About 180 CRS oedometer tests and 360 triaxial tests were performed. These results generally show good to excellent sample quality. However, due to the interpreted lower values of undrained shear strength from local CPTU correlations, 9 block samples were retrieved at 3 locations and additional laboratory testing was performed. The active undrained shear strength obtained from the block samples was up to 53% higher. Based on this data set, correlations were established to optimize the engineering solutions for the new road and to address the impact of sample disturbance on geotechnical engineering parameters. The results lead to important economical saving for the project and highlight the need for local and high quality samples for CPTU correlations in soft and sensitive clays.

1 INTRODUCTION
All building and construction works require reliable and proper determination of geotechnical design parameters. A careful consideration of the most appropriate investigation method is likely to result in improved understanding of soil behaviour and, therefore, in more cost-effective and sustainable solutions for the construction, transport and energy sectors. There is a need for better understanding of the behavior of soft and sensitive clays in order to improve geotechnical design, make it more innovative, and to reduce risks related to e.g. landslides and excavation failures.

NGI was recently involved in the elaboration of the detailed zoning plan for the new highway, E16, from Nybakk to Slomarka (approximately 50 km northeast of Oslo, Norway). Samples were collected using a piston sampler (Ø72 mm) at c. 70 localities and CPTU soundings were carried out at over 120 locations. About 180 CRS oedometer tests and 360 triaxial tests were carried out to assess the strength and stiffness properties of the Rakkestad clay along this E16 section. The results generally show good to excellent sample quality. However, the undrained shear strength interpreted from local CPTU correlations and based on the laboratory results was about 15% less than expected from previous experience.

To evaluate the impact of sample quality on the CPTU correlations, nine block samples (Sherbrooke type; Ø250 mm) were retrieved at three locations and additional laboratory testing was performed on the clays. This would allow for an optimization of the chosen design parameters and thereby optimize engineering solutions in connection with the construction of the new road.

The goals of the present paper are to demonstrate and document the impact of sampling methods on the stiffness and strength properties of the Rakkestad Clay, and to give recommendations on the most appropriate CPTU correlations for assessing the strength and stiffness properties of this clay. The results lead to important economical saving for the project and highlight the need for local and high quality samples for CPTU correlations in soft and sensitive clays.

2 STUDY AREA AND DATA INCLUDED IN THIS STUDY
The location of the planned highway, E16, from Nybakk to Slomarka is shown in Figure 1. The soil conditions in the study area are fairly homogenous and can be generalized with three layers. The top layer consists of a 0.4 m thick cropland overlying a layer of desiccated clay or dry crust underneath.
The dry crust generally extends 3–4 m below the ground surface. Further down, a normally consolidated and sensitive marine clay is found. The sensitivity (Sₜ) of the clay varies in this deeper layer (Sₜ up to 230) and the clay is also found to be quick (i.e. remolded undrained shear strength; sᵤ < 0.5 kPa) at certain localities and depths. Aging may have led to some overconsolidation in the clay. The thickness of the marine clay deposit varies from approximately 20 to 45 m below the ground surface.

A high number of undisturbed samples were retrieved from 102 boreholes with an Ø72 mm GEONOR piston sampler. The compiled database with results from tests on 72 mm samples is further referred to as the Reference database.

To evaluate the effect of sample quality on the strength and stiffness characteristics of the clay, Ø250 mm Sherbrooke block samples were retrieved at three locations along the planned E16. These locations are referred to by their borehole identification numbers which are 2371, 2411 and 2284. All block samples were carved at similar depths as the previously retrieved 72 mm samples and are representative of the general soil conditions in the study area.

3 GEOTECHNICAL PROPERTIES OF THE CLAY

3.1 Index properties

The water content of the clay samples in the study area ranges from 30–45% while the total unit weight varies between 17.5 and 19.5 kN/m³.
3.3 Strength properties

Typical results from anisotropically consolidated triaxial tests sheared in compression (CAUC) are shown in Figure 4 for both 72 mm samples and block samples from the same location and depth. According to the sample quality criteria proposed by Lunne et al. (1997) all samples were categorized as being of good to excellent quality. All stress-strain curves on Figure 4 show a strain softening behavior for the Rakkestad clay. However, results from CAUC tests on block samples show a higher peak shear strength and a more brittle behavior than those on the 72 mm samples (Fig. 4). The difference in peak strength can be important and was observed to be up to 53.8% at some locations (Table 1).

Figure 5 illustrates the undrained shear strength ratio \( (s_u/p_o') \) from triaxial tests (CAUC) as a function of OCR.
4 CPTU CORRELATIONS

4.1 Correlations for OCR

CPTU correlations for assessing OCR in Norwegian clays have previously been established by Karlsrud et al. (2005). These correlations were established based on CPTU cone factors such as $N_{\Delta u}$, $N_{kt}$, and $N_{ke}$ and a large database of block samples with overall similar soil conditions as those found herein. However, in this study, all form of correlations between OCR and the CPTU cone factors were found to be poor (i.e. very low regression coefficient; $r^2$). The best fit regression result was obtained between the normalized cone parameter $Q_t$ and OCR (Fig. 6) through the following equation:

$$OCR = 0.35 + 0.645Q_t \quad r^2 = 0.95 \quad (1)$$

where $Q_t = (q_t - \sigma_v) / \sigma_v'$, $q_t$ with being the corrected cone resistance, $\sigma_v$ the total vertical stress and $\sigma_v'$ the vertical effective stress.

As shown on Figure 6, the trendline of Equation 1 is very similar to the $Q_t$-OCR trendline defined by Karlsrud et al. (2005) for clays with sensitivity higher than 15. One can also note little variation in the block sample data compared to the 72 mm data points. For a given a value of $Q_t$, the best regression line for the 72 mm reference database provides a much lower OCR value (i.e. black line in Fig. 6).

Figure 7 presents a regression of data based on the pore pressure parameter $B_q$, $I_p$, and the OCR. The regression analysis shows a fairly high regression coefficient, only slightly lower than $r^2$ for Equation 1. The best fit is given as:

$$OCR = 16.5 \cdot B_q^{-2.85} \cdot I_p^{0.75} \quad r^2 = 0.84 \quad (2)$$

Figure 8 shows the excess pore pressure $\Delta u$ measured at location $u_1$ against undrained shear strength from CAUC triaxial tests.

Once again, the results from block samples show more consistent results than those from the 72 mm reference database.

4.2 Correlations for undrained shear strength in compression ($s_u^c$)

Figures 8 and 9 illustrate the excess pore pressure and the net cone resistance against the measured undrained shear strength in compression ($s_u^c$) from the study area. From these figures, one can see that the undrained shear strength data correlates better (higher coefficient of determination; $r^2$) with the $\Delta u$ parameter. On these figures, a larger scatter
can also be observed in the reference database compared to the larger diameter block samples data set. To evaluate the most appropriate equation form for the interpretation of $s_u$ from CPTU data in the study area, a series of regression analyses were performed. The two best fits were obtained by using i) the $\Delta u$ parameter with OCR, and ii) the $q_{net}$ parameter with OCR. The resulting best fit equations are given as follows:

\[ s_u = 4.82 + 0.11\Delta u + 1.38\text{OCR} \quad r^2 = 0.93 \quad (3) \]

\[ s_u = 0.39\text{OCR}^{0.17}q_{net}^{0.83} \quad r^2 = 0.74 \quad (4) \]

As shown from the $r^2$ coefficients above, the best statistical fit is obtained with Equation 3 on the basis of the $\Delta u$ parameter and OCR data. Figures 10 and 11 shows that both Equations 3 and 4 gives reliable estimates of $s_u$ in the study area, within $\pm 10\%$ of that measured in the laboratory from CAUC on block samples.

### 5 DESIGN CONSIDERATIONS

A typical example of the use of Equations 1–4 in the study area is shown in Figure 12 for a CPTU test carried out at location 2371. On this figure, the OCR and $s_u$ interpretations are compared to results from other empirical correlations normally used in design in Norway (i.e. Karlsrud et al. 2005) and to correlations based on laboratory results from 72 mm samples. The latter is based on the best fit $N_{\Delta u}$ correlation (i.e. $N_{\Delta u} = \Delta u/s_u$) shown in Figure 8.

As expected, a better match with the relationships based on the block sample correlations is obtained. The Karlsrud et al. (2005) relationship seems to underestimate the OCR of Rakkestad clay. The differences are significant throughout the profile (Figure 12).

Differences are also observed in the case of the interpreted undrained shear strength (Figure 12). Here the difference can be up to 30–40% when compared to the interpretation based on the 72 mm reference database. Also, at depths larger than 10 m, the estimated shear strength from Equations 3–4 is generally higher (up to 30%) than that obtained from the Karlsrud et al. (2005) methodology.

The major difference between the undrained shear strength estimated from the 72 mm reference data-
A high quality database including results from CPTU and laboratory tests performed on Ø72 mm piston samples and Ø250 mm block samples collected along the planned new highway, E16, from Nybak to Slomarka, in southeastern Norway was assembled. The laboratory results on block samples show a superior quality compared to 72 mm samples, a higher peak undrained shear strength and less scatter in the other important geotechnical parameters such as preconsolidation stress and overconsolidation ratio.

Based on regression analyses, the database allowed the development of empirical correlations between CPTU parameters and the undrained shear strength and the overconsolidation ratios for the Rakkestad clay. The recommended CPTU correlations in the study area show up to 40% increase in undrained shear strength when compared to previously established CPTU correlations for Norwegian clays, or to correlation based on laboratory tests performed on 72 mm samples.

Results presented herein clearly show the importance of establishing site specific correlations when assessing geotechnical parameters from CPTU tests. In soft and sensitive clays, it is also particularly important that the correlations are established from large diameter samples of very high quality. For the E16 project, a small investment in the field campaign to collect large diameter block samples will lead to cost-effective solutions and savings of approximately 30% associated with the lime-cement stabilization of road cuttings.
